The concept of *adaptation* is central to evolutionary psychology. Three types of developmental adaptations are described: *ontogenetic adaptations*, *deferred adaptations*, and *conditional adaptations*. Adaptations develop and are based on the highly plastic nature of infants' and children's behavior/cognition/brains. The concept of *evolved probabilistic cognitive mechanisms* is introduced, defined as information-processing mechanisms evolved to solve recurrent problems faced by ancestral populations that are expressed in a probabilistic fashion in each individual in a generation, based on the continuous and bidirectional interaction over time at all levels of organization, from the genetic through the cultural. Early perceptual/cognitive/affective biases result in behavior that, when occurring in a species-typical environment, produce adaptive changes in behavior and cognition, yielding stable and adaptive outcomes. Examples from three domains, the development of face processing in infancy, prepared fears, and tool use, are

provided illustrating the development of adaptations via evolved probabilistic cognitive mechanisms.

Introduction

Central to Darwin's idea of evolution by natural selection is the concept of *adaptation*, traits that promote survival and reproductive success. Needless to say, the concept of adaptation is also central to evolutionary psychology. Following Buss and his colleagues (1998), "An adaptation may be defined as an inherited and reliably developing characteristic that came into existence as a feature of a species through natural selection because it helped to directly or indirectly facilitate reproduction during the period of its evolution" (Buss et al. 1998, p. 535). Although mainstream evolutionary psychologists quite understandably focus on adaptations during adulthood – this is where the mating, competition for social dominance, and child-rearing take place, after all – adaptations also characterize childhood. In fact, until relatively recent times, childhood mortality was about 50%, making childhood the "crucible for natural selection" and thus likely the source of many adaptations.

In addition to describing different types of developmental adaptations in this entry, the developmental origins of adaptations will also be examined. Adaptations may be inherited, as claimed by Buss and his colleagues in the aforementioned quote, but they do not arise fully formed. Rather, from a developmental perspective, adaptations develop in a species-typical way when the organism experiences a species-typical environment (Bjorklund 2015). Infants and young children are biased by natural selection to process some information differently from other information, and such biases contribute to the development of adaptive species-typical behavior when children grow up in species-typical environments. Also to be discussed is how the plasticity of children's brains and cognition permits a range of potentially adaptive outcomes, dependent on the specific environments that children experience.

Adaptations of Infancy and Childhood

Not all adaptations are created equal. Evolutionary developmental psychologists have identified three types of adaptations associated with infancy, childhood, and adolescence: ontogenetic, deferred, and conditional.

Ontogenetic Adaptations

Ontogenetic adaptations serve an adaptive function at a specific time in development and disappear when they are no longer functional (Bjorklund 1997). They function essentially to keep the organism alive or to help it adjust to its current environment rather than preparing it for life in a future environment. Many aspects of prenatal functioning are good examples of ontogenetic adaptations. For instance, the yolk sac of birds and the placenta and umbilical cord of mammals serve obvious adaptive functions when the animal is in the egg or the uterus but are discarded after birth, being replaced by other adaptive physiological functions for respiration and nutrition. Newborns' tendency to copy facial expressions of adults (neonatal imitation, Meltzoff and Moore 1977) has been interpreted by some, not as a "true" form of social learning, but as reflexive-like behavior that serves to promote social interaction between an infant and its mother during a time when the infant cannot control its own social behavior. Support for this position comes from evidence that copying a models' facial expressions decreases to chance levels by about 2 months of age and that infants who displayed higher levels neonatal imitation show better social interactions with their mothers 3 months later (see Bjorklund 1997).

Ontogenetic adaptations are not limited to infancy but can be seen in older children as well. For example, preschool-age children consistently overestimate their physical, social, and cognitive abilities, thinking that they are smarter, stronger, and more popular than they really are, and such overestimation has some positive consequences. For example, in one study, preschool children who overestimated their imitative abilities had higher verbal IQ scores than more accurate children (Bjorklund et al. 1993), and preschool and

early school-age children who overestimated how many items they had remembered on early memory trials had higher levels of memory and strategy performance on later trials than more accurate children (Shin et al. 2007). Children's overly optimistic opinions of their own abilities presumably enhance their self-efficacy, causing them to persist on tasks and in situations where a child with a more accurate assessment of his or her less-than-stellar functioning might quit. (See the entry on ► ["Ontogenetic Adaptations,"](#) in this volume.)

Deferred Adaptations

In contrast to ontogenetic adaptations are deferred adaptations, which serve to prepare infants and children for life as an adult or for the acquisition of important skills that will be useful throughout life (Hernández Blasi and Bjorklund 2003). Sex differences are clear candidates for deferred adaptations, with boys and girls having different biases that direct them to different activities that will prepare them for life as an adult (or would have prepared them for adult life in the environment of evolutionary adaptedness). For example, in traditional environments, children learn much about how to function as an adult through play with age-mates. Play itself can be viewed as a deferred adaptation, for both boys and girls. However, although there are many similarities between the play of boys and girls, there are also differences. For example, boys engage in more vigorous rough-and-tumble play than girls, which some scholars have proposed prepared ancestral boys for adult fighting. Both boys and girls engage in fantasy play during childhood. Such play involves counterfactual thinking, and Nielsen (2012) proposed that fantasy play, along with imitation, was responsible in part for the evolution of the modern human mind. However, there are sex differences in the themes of play, with girls across cultures engaging in more play-parenting and nurturing roles, whereas boys' play is usually centered on aggression and domination themes. Such play, in addition to helping children navigate social hierarchies and develop relationships (which serve both immediate and deferred functions), helps children learn the roles they will likely play as adults or would have played in ancient

environments. These adaptations should not be viewed as being impervious to experience or as producing inevitable outcomes. Rather, they are better viewed as biases that can be modified by experience, reflecting the high degree of neural, cognitive, and behavioral plasticity characteristic of childhood (see further discussion to follow).

Conditional Adaptations

Conditional adaptations can be thought of as a type of deferred adaptation, but ones that emphasize the importance of children's plasticity and sensitivity to local environments and children's ability to adjust their developmental trajectories in anticipation of future contexts. Boyce and Ellis (2005) defined conditional adaptations as "evolved mechanisms that detect and respond to specific features of childhood environments – features that have proven reliable over evolutionary time in predicting the nature of the social and physical world into which children will mature – and entrain developmental pathways that reliably matched those features during a species' natural selective history" (p. 290).

Perhaps the most studied topic from this perspective is the effect of early rearing environment on the rate at which children (especially girls) attain puberty and subsequent mating and parenting strategies. For example, Belsky et al. (1991) proposed that economic and social-relational (e.g., parental warmth, dependability) conditions during the first 5–7 years of life are good predictors of subsequent environments and direct children to develop either a "fast" (early attainment of puberty, early sexual debut, relatively little investment in partners or children) or a "slow" (later attainment of puberty, delayed sexual activity, greater investment in partners and children) *life history strategy*. Although following a fast life history strategy may be seen as maladaptive from a societal or mental-health perspective, it may be adaptive from a biological/evolutionary perspective, or would have been for our ancestors. Children growing up in harsh and unpredictable environments may be better served by reaching maturity early, not depending on long-term support from mates, and having a greater number of children in whom they invest

relatively little (i.e., a "quantity vs. quality" approach). The opposite pattern would likely be adaptive for children growing up in supportive, predictable, and high-resource homes. More than two decades of research has generally confirmed this hypothesis (see Ellis et al. 2009, 2012), highlighting the importance of developmental plasticity as a function of early rearing conditions. Such adaptive plasticity is even found before birth, with researchers reporting that prenatal experiences can influence postnatal taste preferences, caloric metabolism, and attachment patterns (see Gluckman and Hanson 2005). As Del Giudice (2012, p. 1615) suggests, "The developing fetus can use this information as a 'forecast' of the environmental conditions it will eventually face after birth, and start adjusting its physiological and behavioral profile to match the requirements of the world it will probably encounter."

Although the concepts of ontogenetic, deferred, and conditional adaptations provide valuable ways for thinking about how natural selection may have operated over the life cycle and how contemporary children are prepared by natural selection at different points in their development, the distinctions are not always clear-cut. Moreover, even if an adaptation does prepare a child for adulthood, for example, it also likely provides some immediate benefit. For instance, most forms of social play help children learn how to navigate social hierarchies, settle disputes, and solve problems, all great preparation for adult life. However, the same social play also helps children deal with their immediate environment, and similar arguments could be made for some ontogenetic and conditional adaptations. For example, although certain aspects of attachment seem clearly well suited to foster a child's immediate survival, individual differences in attachment-related behaviors may help children anticipate future environments, as proposed by Belsky and his colleagues.

What Are Psychological Adaptations Made Of?

Unlike adaptations such as an umbilical cord or an opposable thumb, there are no easily identifiable

physical manifestations for psychological adaptations. Evolutionary psychologists have proposed that what underlie psychological adaptations are *evolved cognitive mechanisms* – information-processing mechanisms shaped by natural selection over evolution to solve recurrent problems faced by our ancestors associated with reproduction and survival. According to Tooby and Cosmides (1992, p. 277), evolved cognitive mechanisms “in interaction with environmental input, generate manifest behavior. The causal link between evolution and behavior is made through psychological mechanisms.” Such mechanisms are described as being *modular*, consisting of domain-specific cognitive abilities that evolved in response to specific recurrent adaptive problems.

One problem that some developmental psychologists have with the concept of evolved cognitive mechanisms is the implication of *genetic determinism* – such mechanisms are perceived as reflecting innate processes that are activated at appropriate times and in specific contexts to produce adaptive outcomes, leaving little room for the role of experience in shaping adaptive phenotypes. Although mainstream evolutionary psychologists rightly chafe at the label “genetic determinist,” the standard notion of evolved cognitive mechanism fails to capture the substantial role of plasticity that is seen in the development of adaptations. In response, Bjorklund et al. (2007) proposed the concept of *evolved probabilistic cognitive mechanism*, defined as

information-processing mechanisms that have evolved to solve recurrent problems faced by ancestral populations; however, they are expressed in a probabilistic fashion in each individual in a generation, based on the continuous and bidirectional interaction over time at all levels of organization, from the genetic through the cultural. These mechanisms are universal, in that they will develop in a species-typical manner when an individual experiences a species-typical environment over the course of ontogeny (p. 22).

Evolved probabilistic cognitive mechanisms share most features with evolved cognitive mechanisms as mainstream evolutionary psychologists define them; the major difference being that a cognitive mechanism’s expression is explicitly

probabilistic, dependent upon bidirectional interactions between all levels of the organism-environment system. From this perspective, what are inherited are perceptual/cognitive/behavioral biases or dispositions that interact with a child’s environment, producing a pattern of, usually adaptive, thinking or behavior. Children are sensitive to specific types of information at particular times in development, resulting in a choreographed dance between gene-influenced neural maturation and species-typical experience. This is why most members of a species, be they monkeys, geese, or humans, grow up to be much alike one another – they inherit both a species-typical genome and a species-typical environment. However, because of the high level of neural plasticity of infants and children, developmental outcomes are not predetermined but can vary, often in adaptive ways, as a result of variations in early experiences. Such sensitivity to early experiences and the ability to modify one’s developmental trajectory are critical for a species, such as humans, who live in a vast range of both physical and social environments. From this perspective, evolved probabilistic cognitive mechanisms are not viewed as encapsulated modules, but rather as emerging from initial perceptual and information-processing biases in interaction with species-typical environments. Thus, evolved probabilistic cognitive mechanisms, and the adaptations they underlie, develop, with the eventual form of an adaptation being dependent upon a history of experience.

The following sections provide some examples of how evolved probabilistic cognitive mechanisms may develop in the domains of infant face perception, prepared fears, and tool use, leading to adaptive outcomes. For a more in-depth discussion, please see Bjorklund (2015).

Infants’ Development of Face Processing

For a social species such as ours, with infants who are highly dependent on adult care, few stimuli can be of more significance than the human face. Newborns begin life with perceptual biases that attract them to faces, and they give special

processing priority to faces. For example, shortly after birth, neonates (1) show a bias to look at face-like stimuli (e.g., schematic stimuli with two dots placed over a single dot within a headlike figure vs. when the dots in the figure are inverted); (2) are especially attentive to faces with eyes open and gazing at them; (3) look longer at right-side-up versus inverted faces, but only when they can see the eyes; (4) spend more time looking at their mothers' faces than at faces of other women; and (5) discriminate between human and nonhuman faces (see Bjorklund 2015). This pattern does not necessarily mean that newborns understand the conceptual meaning of faces. Rather, faces appear to have certain perceptual features that attract young infants' attention, including movement and areas of high contrast, such as eyes. By 3 or 4 months, infants show a bias to attend to curvilinear stimuli and vertically symmetrical stimuli (i.e., the right and left sides of a stimulus are symmetrical) and have biases to attend to "top-heavy" stimuli (i.e., up-down asymmetry), with this bias being found even in newborns (see Bjorklund 2015).

Infants' abilities to discriminate among faces improve over the first 5 or 6 months of life and become especially good for the types of faces they see on a regular basis. For example, at 6 months of age, infants are able to discriminate between upright and upside-down faces of both humans and monkeys (Pascalis et al. 2002). By 9 months, infants are increasingly able to discriminate between human faces but now process upright monkey faces no differently than inverted monkey faces (Pascalis et al. 2002), reflecting more specialized processing with experience. Similarly, infants are better able to distinguish among the more-familiar females faces than the less-familiar male faces, unless fathers are the primary caretakers. According to Pascalis and his colleagues (2002, p. 1321), "the ability to perceive faces narrows with development, due in large measure to the cortical specialization that occurs with experience viewing faces. In this view, the sensitivity of the face recognition system to differences in identity among the faces of one's own species will increase with age and with experience in processing those faces."

A similar pattern of development is found for infants' ability to tell the difference between faces of people of their own race versus those of another race (the *other-race effect*). For instance, in one study (Kelly et al. 2007), 3-month-old Caucasian infants were able to discriminate adult faces from among four ethnicities (African, Middle Eastern, Chinese, Caucasian). By 6 months, infants were able to distinguish between Chinese and Caucasian faces but not between African or Middle Eastern faces, and at 9 months, they performed greater than chance only for the Caucasian faces. That experience with specific classes of faces was the primary reason for the development of the other-race effect is demonstrated by research that exposed infants to photos of faces from other races or other species and reported subsequent abilities to discriminate "foreign" as well as same-race (or same species) faces (e.g., Anzures et al. 2012). Thus, infants are initially able to make discriminations equally well for faces of different species, sexes, and ethnicities, but with experience, their processing narrows, increasing their ability to discern differences among faces they see regularly, whereas they become relatively less facile making discriminations among faces they see less frequently.

Newborns seem to know nothing about faces, per se, although they are attracted to and process more efficiently lower-level features that happen to be associated with faces. With experience, they become increasingly able to discriminate faces, especially those from groups of individuals with which they regularly interact (humans, women, members of their own race), while at the same time reducing their ability to process the types of faces they encounter only occasionally. Yet, infants retain enough plasticity that developmental trajectories can be modified, permitting Caucasian infants, for example, to maintain (or regain) their ability to differentiate between faces from a different race or even a different species.

Developing Prepared Fears

There seem to be some things that infants fear, or show heightened levels of distress for, with little or

no previous experience. These include loss of support and loud noises. Other fears seem to develop somewhat later but appear to be nearly universal, including fear of snakes and spiders. But do people actually have an innate fear of snakes or, like the processing of faces, do initial perceptual bias make acquiring such fears more likely?

Much as rats seem prepared to associate nausea with previously eaten food, monkeys that initially show no fear of snakes are more likely to respond fearfully after watching another monkey respond with fright to a snake than to a rabbit or a flower (Cook and Mineka 1989). Research indicates that adults, children, and infants identify snakes (and spiders) more quickly from an array of flowers than vice versa (see LoBue 2013). Such biases seem to extend to sounds as well. For example, in one study, 9-month-old infants were more attentive to evolutionarily fear-relevant sounds (e.g., crackling fire, hissing snake) than to modern fear-relevant (e.g., tires screeching, bomb exploding) or pleasant (e.g., Beethoven or rock-and-roll music, horse neighing) sounds (Erlich et al. 2013). Other research shows that people more easily acquire fear responses for evolutionarily relevant objects, such as snakes, than for objects that may be more dangerous in contemporary environments, such as guns, knives, and automobiles.

Yet, rather than being innately fearful of snakes and other evolutionarily relevant stimuli, it seems that humans (and monkeys) have a tendency to learn to associate such stimuli with fearful responses. For instance, in one study (DeLoache and LoBue 2009), 7- to 9-month-old infants and 14- to 16-month-old toddlers viewed videos of snakes and other animals (rhinoceroses, giraffes). Although the children initially displayed no fear of the snakes (in fact, infants and young children without previous negative experience with spiders and snakes are often highly interested in these animals, see LoBue 2013), when they saw short video clips of snakes and other animals paired with either a fearful or happy voice, they looked longer at the snakes when listening to the fearful voice than the happy voice. There was no difference in looking time to the two voices when they watched videos of other animals. Similar patterns

were reported for infants with respect to angry/fearful faces: infants more readily identified images of angry faces than happy faces (LoBue and DeLoache 2010), and 11-month-old girls more easily associated a spider or snake with an image of a fearful face than an image of a happy face (Rakison 2009).

It seems highly unlikely that infants enter world fearing snakes, spiders, or angry/fearful faces. Rather, such fears are learned, as much as fear for other stimuli is learned. However, primate infants appear to possess perceptual biases increasing the probability that fearful responses to these evolutionarily relevant stimuli will be learned.

Children as Tool Users

All animals must learn to deal with objects in their physical world, but many, perhaps most, of the objects that humans encounter are *cultural artifacts*, things made by people for a specific purpose. One large category of cultural artifacts is *tools*, devices used for “doing work” or solving specific problems. As soon as infants have sufficient motor dexterity, they begin to manually explore objects (“What can the object do?”), discovering their affordances (i.e., functional relationships between objects and the environment) along the way. This is followed beginning around 9-months of age by manual play (“What can I do with the object?”) (Belsky and Most 1981). Although estimates vary, approximately one-third of preschool-aged children’s activity involves playing with objects, with similar values being reported for children in hunter-gatherer societies (Bock 2005).

One purported purpose of object play is to allow children to discover the affordances of objects, which may facilitate subsequent tool use. For example, researchers reported that 5- and 6-year-old children were more likely to appropriately modify a tool (bend a pipe cleaner so it can be used as a hook) when they were given the chance to explore the properties of the object beforehand, in conjunction with observing a model using the tool, than children not permitted

to manipulate the materials (Cutting et al. 2014). In other research, Gredlein and Bjorklund (2005) measured the amount of object-oriented play in 3-year-old children during a free-play session, and then, in a separate session, assessed children's ability to select and use a proper tool to retrieve an out-of-reach toy. They reported that boys performed the tool-retrieval task better than girls (although girls performed comparably after a simple hint) and that there was a positive correlation ($r = 0.59$) between the amount of object-oriented play during the previous free-play sessions and performance on the tool-retrieval task for boys, but not for girls, causing Gredlein and Bjorklund (2005) to suggest that boys may be more sensitive to such environmental experiences than girls.

Infants and young children are not only motivated to interact with objects, but early in development, they learn that an artifact that is used to solve a problem was in fact designed for a specific function, referred to as the *design stance*. Children acquire the design stance for new tools relatively early. For example, when shown a new object and told of its function (e.g., a boxlike object used for catching bugs), 3-year-old children are less likely to see an alternative use for the object (e.g., collecting raindrops), associating it with its originally designed purpose. Their prior knowledge of what spoons are "for" resulted in what is referred to as *functional fixedness*, a lack of flexibility when it comes to using a familiar tool. Functional fixedness is generally thought of as a "mental block" that hinders effective problem solving. However, the design stance, though sometimes resulting in overly rigid behavior, more typically results in adaptive outcomes. By identifying what a particular artifact is "for," children (and adults) can more efficiently use tools that were in fact designed for a specific purpose.

Children's biases to manipulate objects, to discover their affordances, and their early design-stance orientation are associated with social-learning abilities in acquiring proper tool use. From at least 3 years of age, children readily learn how to use novel tools from watching models (e.g., Flynn and Whiten 2008). In fact,

preschool children tend to copy *all* behaviors associated with a model, whether relevant or not, which has been referred to as *overimitation*. Children assume that all of a model's behavior are normative and assume (usually correctly) that someone would not purposefully perform unnecessary actions.

Effective tool use in humans is nearly inevitable, but it is not based on an innate "tool-use" adaptation unique to our species. Rather, infants have biases to manipulate objects, with the purpose of both seeing what objects can do (exploration) and what they can do with the objects (play). In the process, they discover affordances of the objects and develop action plans for using these objects. As children become able to mentally represent objects, their general tendency to see purpose in the objects and events in the world make it increasingly likely that they will learn to use objects as culturally prescribed. This is further facilitated by social-learning biases that result in children viewing the actions of others as normative and worthy of often precise imitation.

Conclusion

The concept of adaptation is central to evolutionary psychology. However, due to the high levels of children's behavioral, cognitive, and neural plasticity, the final form (most) adaptations take will depend on the early and continuous experience of children on their way to adulthood. Infants and children with species-typical genomes possess low-level perceptual or cognitive biases or abilities, which, in interaction with their environment, lead most children to process effectively faces from their own species or ethnic group, to acquire fearful responses to specific evolutionarily relevant stimuli, or to develop a facility with tools.

Although the examples provided here may more easily fit the definition of evolved probabilistic cognitive mechanisms than others, the process is a general one, reflecting how many adaptive

behaviors and cognitions are acquired and have been acquired over the course of human evolution. For example, there are a number of low-level perceptual and cognitive traits that underlie social relations in infancy, in addition to the face-processing mechanisms discussed earlier. These include neonatal imitation, discussed previously as an ontogenetic adaptation, a bias to attend to biological motion, and baby-like facial features that promote caregiving. Similarly, the social-learning biases that foster rapid acquisition of tool use via observation are preceded by more basic abilities such as infants viewing others as intentional agents – individuals whose actions are performed to achieve some goal (Tomasello 2009) and are reflected by the development of perspective taking, social referencing, and shared attention.

From the current perspective, evolutionary adaptations are emergent properties, arising from low-level perceptual and cognitive biases, with children themselves playing an active role in these adaptations' development (and evolution), through continuous interaction with their physical and social environments.

Synonyms

Aggressive behavior; Etiology of aggression; Proactive aggression; Reactive aggression

Definition

Aversive behavior that may harm another organism.

Introduction

Aggressive behavior is ubiquitous across species. While animal models present a clear definition of aggression as any behavior that is aversive and may inflict harm on another organism, human aggression proves more difficult to define. The challenges of defining human aggression result from a combination of philosophical differences among academics, the difficulties associated with defining a complex behavior, and the challenges of assigning motivation that cannot be readily observed (Olivier and Young 2002). Human aggression is typically classified into two categories: *reactive aggression* and *proactive aggression*. Reactive aggression, or *affective aggression*, is theoretically rooted in Berkowitz's (1993) frustration-aggression model and is described in the literature as defensive and angry behavior in response to provocation. Proactive aggression, or *predatory aggression*, is theoretically rooted in Bandura's (1973) social learning theory and is described as deliberate, goal-directed, and often unprovoked.

Is Aggression Adaptive?

While the adaptiveness of aggression is subject to much debate, perhaps this question is best answered by clarifying what is meant by *adaptive*. According to Darwin's theory of evolution, variability in reproductive success within a population is necessary for natural selection to occur. The extent to which an organism is reproductively successful is referred to as *genetic fitness* (Silk 1986). Given the frequency and prevalence of aggression, it is likely an adaptation that conferred some sort of reproductive advantage to those who expressed it. Thus, if aggression improves reproductive fitness, it is considered adaptive.

Animal Models of Aggression Development

Aggression is expressed ubiquitously across the mammalian animal kingdom (Veenema 2009). *Offensive aggression*, which is similar to proactive aggression among humans, may be displayed by adult males who are defending resources such as food, mates, or territory. Similarly, predatory aggression is a form of goal-directed aggression displayed by animals while hunting for prey. *Defensive aggression*, which is similar to reactive aggression among humans, is displayed when animals are attacked by predators or conspecifics. *Maternal aggression* is a type of defensive aggression and is displayed by females to protect their young from potential intruders (Veenema 2009). These types of aggression are functionally and phenotypically distinct from each other and likely are associated with differing activation of underlying neuroendocrine systems (Veenema 2009).

Among captive groups of rhesus monkeys and pigtail macaques, there is a 5–10% rate of child abuse or neglect. Among pigtail macaques, incidents of abusive behavior increase following a stressful event, such as an attempted kidnapping of a child or intergroup aggression (Maestriperi 1998). Similarly, abusive mothers among Japanese macaques display higher levels of anxiety

than their non-abusive counterparts. Furthermore, abusive behavior decreases or ceases after the administration of anxiolytic medication (Troisi et al. 1991). Early experience appears to play a fundamental role in the etiology of abuse and neglect of one's kin that is demonstrated by a pattern of early experience accounting for more variation in abusive behavior than genetic inheritance (e.g., Veenema 2009). Taken together, these results suggest that early abuse contributes to a pattern of emotional dysregulation that may be exaggerated under conditions of stress (such as motherhood), which contribute to the development of aggression and neglect of one's kin.

Classic experiments conducted by Harlow & Harlow (1965) demonstrated the immense impact of early separation on typical development, leading to an increased likelihood of inappropriate displays of aggression later in life. The typical paradigm of maternal separation in animal experiments is "repeated maternal separation," which consists of removing a child from their mother for 3 hours a day, every day for the first 2 weeks of life. Experiments that utilize this paradigm with rodents have demonstrated that maternal separation leads to increases in aggressive behavior later in life. For example, male Wistar rats that experienced repeated maternal separation as infants displayed increased play-fighting as juveniles and intermale proactive aggression as adults (Veenema et al. 2007; Veenema and Neumann 2009). Similarly, while these results were not replicated among C57B1/C mice, repeated maternal separation as an infant did appear to contribute to increased maternal aggression during the first 2 weeks of lactation as an adult (Veenema et al. 2007).

Development of Aggression Through the Life Span

Prenatal Factors

Broadly speaking, the environment may interact with individual differences to produce aggressive responses. As such, displays of aggressive behavior represent a host of interacting biological,

psychological, and social factors. The adaptive perspective posits that aggression is highly context-specific and is only elicited in situations in which specific adaptive problems are confronted, for example, to defend against attack, inflict costs on intrasexual rivals, or negotiate power status (Buss and Shackelford 1997).

From a neurological perspective, researchers suggest that aggression is influenced by a system of glands in the nervous and endocrine systems that regulate stress responses called the hypothalamic-pituitary-adrenal (HPA) axis. Factors that negatively affect the development of the HPA axis include fetal exposure to environmental toxins, maternal substance use, and prenatal maternal stress. As a result, these factors are associated with long-term consequences on HPA functioning, including increased stress reactivity, negative emotionality, and behavior problems across the life span (Labella and Masten 2018).

Early Childhood

While controversial, some developmental scientists view early aggression as a developmental milestone (e.g., Hay 2017). Displays of aggression begin as early as an infant is able to control their bodily force in a productive manner. By the midpoint of the second year of life, infants are able to reach out to touch and grasp objects and people intentionally (Moszkowski and Stack 2007). Around the same time, they begin to express frustration and distress through facial expression and vocalizations (Stenberg et al. 1983). Soon after, infants can be observed forcefully touching objects, tugging and pulling toys away from others, and pushing, biting, pulling, and hitting (Eckerman et al. 1975). By 2 years old, toddlers can be observed using physical force against peers to attain goals, such as securing a toy to play with, in conflicts (Hay et al. 2011). While mal-intent cannot be ascribed to these actions, the instrumentality demonstrated by visual guiding and direct movement implies goal-directedness and volition in this behavior (Campos et al. 2000). Furthermore, aggression in children as young as 6 months old appears to be stable, as it predicts clinically significant conduct problems and aggression at 3 years old (Hay et al.

2014). Similarly, the first signs of relational aggression begin to appear around 3 years old and become more sophisticated throughout childhood (Crick et al. 2007). As such, early incidents, such as tugging, pushing, and hitting, may be indicative of a long-term developmental pattern of serious aggression (Hay 2017).

Childhood

Postnatally, environmental stressors continue to impact the development of aggression. According to Labella and Masten (2018), familial adversities such as poverty, family stress, disorganization, single parenthood, large family size, and household conflict are all linked to the development of aggression. Furthermore, the impact of environmental stressors on aggression extends beyond the family unit. Witnessing or experiencing violence, personally or through the media, is related to the development of aggression in multiple ways. For example, there are significant links between community violence exposure and increased aggressive behavior (Labella and Masten 2018). Specific interpersonal relationships impact aggression as well. It is well documented that affiliation with antisocial peers is a risk factor for aggression (Lansford 2018). Not only do such environmental factors undermine secure attachment, bias social information processes toward threat detection, and contribute to the dysregulation of the stress response system, but they also offer models of aggression to be imitated and promote the normalization of aggression (Labella and Masten 2018).

Temperament

Temperament appears to be a highly heritable trait, as children who have irritable temperaments may have inherited this trait from their parents. Moreover, an irritable temperament may evoke harsh parenting from a parent who may also have a predisposition toward irritability. A difficult temperament as a child is predictive of reactive aggression later in life. Similarly, children who responded with more negative emotionality than their peers to social and physical disturbances in their environments were more aggressive as preteens (see Vitaro et al. 2006 for review).

The development of aggression is influenced by factors such as self-regulation (effortful and reactive control), emotion states, and personality. There appears to be a salient relationship between aggression and self-regulation, which can be understood as one's ability to accomplish goal-directed behavior when impulses, desires, and habitual patterns of behavior compete for attention (Tirabassi et al. 2017). Research suggests that self-regulation is primarily associated with reactive aggression as a result of deficits in behavioral regulation and future-oriented problem-solving (Tirabassi et al. 2017).

The relationship between self-regulation and aggression may be, in part, a result of low levels of effortful control. Effortful control refers to the regulation of attention and negative reactivity as well as the inhibition of automatic cognitive and behavioral responses. Research suggests that arousing events (prevalent in stressful environments, such as those mentioned above) may make it difficult for individuals to develop the necessary regulatory mechanisms, such as effortful control, to regulate reactive emotions (Esposito et al. 2017). As a result, it may be difficult for individuals with poor effortful control to find non-aggressive solutions to interpersonal problems, including those that are emotionally driven (Loeber and Hay 1997).

The decreased ability to regulate negative emotions is related to the presence of environmental stressors. The resulting emotion dysregulation is predictive of increased levels of aggressive behavior (Lansford 2018). Labelle and Masten (2018) propose that the often emotionally unsupportive nature of early stressful environments contributes to higher levels of distress without a corresponding increase in emotion management (Labella and Masten 2018).

More generally, individuals with poor self-regulation often lack emotional control and may display aggression out of impulse (Wilson and Ray 2018). Likewise, aversive emotional triggers, such as anger or sadness, may elicit fight (i.e., behaving aggressively in response to the emotional stimulus) or flight (i.e., ignoring or retreating from the emotional stimulus) responses (Wyckoff 2016). Specifically, research suggests

that aggression is related to the regulation of negative emotions such as anger, sadness, and frustration. Dane and Marini (2014) suggested that proneness to frustration is associated with an increased risk of aggression, and in individuals with high levels of effortful control, the related behavioral inhibition and planning abilities may actually facilitate aggressive behavior in relational contexts. Furthermore, higher levels of fearfulness appear to play a role in relational aggression, as children who are more fearful may opt to employ more covert forms of aggression such as rumor spreading or exclusion (e.g., Volk et al. 2012). In terms of more positive emotions, research suggests that one's ability to experience and demonstrate empathy influences one's level of aggression (Wilson and Ray 2018). Empathy may act as an influence on aggression in that it facilitates the understanding of others' emotions, thereby potentially inhibiting one's desire to engage in aggressive behaviors directed at others.

Social Information Processing

Crick and Dodge's (1994) social information processing (SIP) model describes a sequence of cognitive processes that are posited to influence social behavior, such as aggression, in children. The five overlapping steps of the SIP model are (1) encoding of external and internal cues, (2) interpretation of those cues, (3) choosing a goal, (4) selecting a response to attain that goal, and (5) performing the response decision (Crick and Dodge 1994). Aggressive children are more likely to demonstrate differences at each of these steps of cognitive processing, such that they may (1) encode social cues as less benign, (2) demonstrate a hostile attribution bias to ambiguous behaviors, (3) select goals that are more likely to damage relationships with others, (4) generate fewer and less prosocial responses, and (5) evaluate aggressive responses that are favorable and expect aggressive behavior to have a positive outcome (Li et al. 2013). Lemerise and Arsenio (2000) extended Crick and Dodge's (1994) model to include the role of emotion and latent cognitive structures in the cognitive processing of social information. They suggested that a critical component of how a child evaluated social behavior is

their emotional style or emotionality. For example, a child who is easily overwhelmed by negative emotion may be more likely to interpret ambiguous behavior as threatening (i.e., Step 2) or choose self-focused responses to these cues (i.e., Step 4). Similarly, internal working models (i.e., mental representations of the self, attachment figures, and how they relate) inform the assumptions aggressive children may hold about their peers. Last, underlying moral knowledge structures are influential in at the response-generation (i.e., Step 4) and response-selection (i.e., Step 5) steps, as the decision on how to proceed will be subject to how the child views the response as impacting future relationships, what extent the perceived provocation is meaningful, and to what extent they will be able to recover from harm (Lemerise and Arsenio 2000).

The aforementioned environmental factors act in conjunction with cognitive distortions to elicit aggression. Cognitive distortions (e.g., hostile attribution bias, evaluating aggressive responses favorably) facilitate aggression by providing individuals with justifications for the ongoing use of aggressive behavior. Koolen et al. (2012) found that in both delinquent and nondelinquent samples, the presence of cognitive distortions was associated with aggressive, offending, and antisocial behavior. Specifically, their research supported that (a) proactive aggression is predicted by egocentric biases (i.e., the belief that one's own needs supersede those of others) and (b) reactive aggression is associated with the misinterpretation of social cues (i.e., hostile attribution bias).

Parental Influence

Reactive aggression appears to be predicted by a harsh and unpredictable environment and abusive or hostile parenting. Retrospective studies on aggressive youth have linked reactive aggression in adolescence with childhood experiences of physical abuse or harsh discipline. However, this is not the case with proactively aggressive youth. Proactive aggression appears to be predicted by supportive environments that allow for aggression to be implemented as a means to achieving one's goals. Similarly, exposure to family members who

model and endorse aggression, and use it to solve conflicts or advance interpersonal relationships, is predictive of later proactive aggression (see Vitaro et al. 2006 for review).

Parents who have traditional attitudes toward gender roles are more likely to reinforce gender role-consistent behavior. This includes reinforcing aggressive behaviors in boys. A study conducted by Endendijk and colleagues (2017) provided evidence to suggest that fathers and mothers with strong stereotypical views on gender roles were more likely to treat their sons and daughters differently in regard to their aggressive behavior. Specifically, parents used more physical control strategies with their sons than with their daughters. As such, boys may come to associate physical control with power and, consistent with social learning theory, may be socialized into traditional male gender roles that emphasize assertiveness and dominance as a consequence (Endendijk et al. 2017; Bandura 1973).

Aggression in Adolescence

From an adaptive perspective, adolescents may be using aggression as an instrumental tool to obtain socially relevant resources. For example, research conducted by Prinstein and Cillessen (2003) suggested that aggressive behavior is associated with higher social status, but lower levels of likability among peers. That is, while adolescents who are aggressive may not necessarily be liked by their peers, they may be choosing to engage in such behavior to attain social status. In other words, any costs associated with aggressive behavior may be outweighed by these benefits (Hawley 2003). Prinstein and Cillessen (2003) also found that there were differences among the subtypes of aggressive behavior. Adolescents who engaged in proactive aggression were more popular, while adolescents who engaged in reactive aggression attained lower levels of social preference. Therefore, it appears that the type of aggressive behavior an adolescent utilizes may be important in determining whether peers reinforce or reject the behavior (i.e., increased social status versus being disliked by peers).

If adolescents who choose to engage in aggressive behavior are rewarded, it may encourage these individuals to continue to utilize aggressive behavior as a means to achieve goals such as social dominance. Recent research has implicated personality as a strong predictor of an individual's willingness to employ aggressive behavior for personal gain across cultures (e.g., Volk et al. 2018).

Personality

Research has suggested that personality factors related to an individual's propensity to exploit and manipulate others for personal gain, unwillingness to cooperate with others, and tendency to favor short-term gains over long-term goals are associated with higher levels of both proactive and reactive forms of aggression (Knight et al. 2018). Similarly, research by Dinić and Wertag (2018) has replicated the result that individuals who are less inclined to cooperate with others are more likely to engage in both subtypes of aggression. Additionally, this research also suggested that individuals who are emotionally detached from others are more prone to engaging in reactive forms for aggression.

A frequent avenue for expressions of aggression, especially among adolescents in the school context, is bullying. A growing body of research is implicating personality as a key predictor of aggressive and antisocial behavior in adolescents (e.g., Volk et al. 2018). Specifically, individuals with personality profiles that include traits associated with the exploitation of others for personal gain and a tendency for reckless and inconsiderate behavior are more likely to engage in bullying behavior in samples of Canadian and Chinese adolescents (Volk et al. 2018). Furthermore, this research supports the evolutionary theory of bullying, which posits that bullying is a facultative adaptation that is used to obtain resources that will ultimately increase genetic fitness, such as material wealth, increased social status, and access to high-quality dating partners, under conducive environmental conditions (Volk et al. 2014).

Aggression in Adults

The way in which aggression manifests and is utilized may be different across the life span, particularly in adulthood. Whereas previous research has suggested that aggression is often stable from childhood to adulthood, other research has proposed that a considerable number of aggressive youth decrease in their aggressive behaviors over time (Loeber and Hay 1997). For example, longitudinal research by Moffit et al. (2002) that examined trajectories of antisocial behavior suggested that there were some differences in the progression from aggressive to delinquent behavior in males. This research found that while engaging in aggressive behavior during adolescence often progressed to delinquency as an adult, there was also another group of men who were low-level offenders as adults and who were aggressive as children but did not engage in delinquent behavior as adolescents. This demonstrates that the trajectory of aggressive behavior during childhood and adolescence to delinquent behavior in adulthood may not always be linear and emphasize the importance of early intervention at the onset of antisocial or aggressive behavior.

It might also be important to consider that certain combinations of gene and environmental interactions during childhood have the potential to result in adults who engage in antisocial behavior. For example, not all children who experience abusive parenting become aggressive adults; however, children who are born with an active monoamine oxidase A (MAOA) gene (an X-linked gene known to inhibit brain chemicals associated with aggression) and experience abuse as a child are more likely to engage in aggressive behavior as an adult than those who experience maltreatment but had an inactive gene (e.g., Byrd and Manuck 2014). Overall, while it is true that some individuals who are aggressive as children may be aggressive as an adult, this type of behavior may be more plastic than earlier research has proposed, and the trajectory may not be linear depending upon the genetic predisposition and experiences of the individual.

Conclusion

Aggression is related to a number of negative outcomes. For children, those that exhibit aggressive behaviors are at an increased risk for continued externalized and problematic behavior (Wilson and Ray 2018). Dane and Marini (2014) posit that aggressive behavior in childhood is related to such negative developmental outcomes as substance dependence, mental health problems, unemployment, inter-partner violence, and criminal offending. However, the frequency and prevalence of aggressive behavior in populations suggests that it would have increased our ancestors' evolutionary fitness – that is, engaging in aggressive behavior would have somehow increased one's chances of propagating their genes onto the next generation. As such, it may be reasonable to suggest that future research endeavors to employ the evolutionary perspective in further understanding the etiological pathways toward aggressive behavior and in designing effective prevention and intervention programs that improve the future outcomes of aggressive children and youth.

Sexual differentiation, development of differences between males and females; Development of sex differences in brain and behavior

Definitions

Activational effects	Transient effects of hormones that occur throughout life.
Asexual reproduction	Offspring produced from a single organism that inherits the entire genome of the parent organism.
Diploid	Having two sets of chromosomes or double the number of chromosomes in the germ cell.
Eusociality	Cooperative breeding strategy in which usually one female and a few males are reproductively active, whereas the rest of the nonbreeding members provide care for the offspring of the colony and gather food and resources for the colony.
Haploid	Having a set of chromosomes equal to the number in the germ cell.
Heterogametic	Refers to the sex of a species that has two different sex chromosomes.
Homogametic	Refers to the sex of a species that has two of the same-sex chromosomes.

Intersexual competition	Mate choice, occurs when an individual is choosing between mates.
Intrasexual competition	Occurs between same-sex individuals competing for a mate.
Monogamous	Mate strategy in which an individual has only one partner at any one time.
Natural selection	Differential survival and reproductive success of individuals due to differences in heritable traits. Key mechanism of evolution.
Organizational effects	Permanent effects of hormones associated with critical developmental periods.
Polygamous	Mate strategy in which an individual has multiple partners at any one time.
Sexual determination	A biological system that determines the sex of an individual. In many species, including mammals, sex determination is genetic.
Sexual differentiation	The development of differences between males and females.
Sexual reproduction	Two organisms generate distinct reproductive cells that fuse together to produce offspring.
Sexual selection	Differential reproductive success due to preferential mate choice of the opposite sex.

Introduction

The development of sex differences is studied by evolutionary psychologists at two levels of analysis: the proximate and ultimate. The proximate level of analysis addresses the ontogeny of sex differences at the level of individuals within a species. At the ultimate level, reasons for the adaptiveness of sex differences and the evolutionary circumstances that lead to sex difference

development are addressed. Both the proximate and ultimate level of analysis will be addressed in this entry, including the evolutionary benefits of having two sexes, as well as evolutionary perspective behind sex differences in size and function.

The Evolution of Sexual Reproduction

Species reproduce in one of two ways, or occasionally in a combination of the two: (1) asexual reproduction by which offspring are produced from a single organism, and (2) sexual reproduction that requires two organisms to generate distinct reproductive cells, called gametes, that fuse together to produce offspring.

The evolutionary advantages of sexual reproduction eluded evolutionary biologists for over a century after the theory of natural and sexual selection was first proposed. Asexual reproduction has many advantages – chiefly, an organism, which has successfully survived to reproductive age in a given environment, produces offspring that inherit all of the parent’s genes with no wasted effort and resources spent on mating. Offspring from asexual reproduction are genetically identical to the single parent, unless any mutations occur during mitotic division. In contrast, with sexual reproduction, only half of the offspring’s genetic material came from each parent. Also, there is the “twofold cost of sex” problem: The offspring output per capita is halved with sexual reproduction because it inevitably requires two individuals, whereas, theoretically, each individual in a species reproduces with asexual reproduction. Furthermore, theoretical analyses suggest that genome mixing is risky, as resulting combinations of genes can be maladaptive. Sexual reproduction also requires a substantial amount of energy and resources devoted to acquiring mating partners.

One advantage of sexual reproduction is that evolution can occur more rapidly with the continuous recombination associated with sexual reproduction, whereas with asexual reproduction the evolution of a species relies on spontaneous mutations. Evolutionary psychologists have found

substantial support for the “Red Queen” hypothesis that explains how recombination through sexual reproduction can be advantageous for the individuals within the species to respond to changing environments, and also to evade evolving predators. Specifically this hypothesis explains that there is an arms race (or co-evolution) between parasites and hosts, and predators and prey, in which genetic recombination allows sexually reproducing species to dispose of deleterious mutations more rapidly and keep mutations that promote survival (For review of this “Red Queen” hypothesis, see Liow et al. 2011). Although evolutionary biologists continue to explore the ultimate reasons for the maintenance of sexual reproduction, it has been proposed that once sexual reproduction arises, it is difficult for a species to then secondarily evolve asexual reproduction (Hörandl 2009), and therefore, most higher order organisms reproduce sexually (For review, see Agrawal 2001; Otto and Thomas 2002).

Proximal Development of Sex Differences

Many species that reproduce sexually have two sexes that contribute to the genetic make-up of their offspring, including genetic information that determines sex. Sex chromosomes are responsible for the cascade of events that determine whether an animal develops into a female or male – a process called sexual determination (For an example of an exception to genetic sex determination, see Holleley et al. 2016). For haplodiploid sex determination, the number of chromosomes determines the sex of the species; males possess a haploid chromosome number, whereas females are diploid. In other species including mammals, birds, and many insects, in which both sexes reproduce through sexual reproduction, both males and females are diploid. When both sexes are diploid, one of the sexes is homogametic (i.e., have two of the same sex chromosome), whereas the other sex is heterogametic (i.e., have two different sex chromosomes). For example, in

birds as well as some fish, insects, and reptiles, females have two different sex chromosomes (Z, W), whereas males have two of the same sex chromosomes (Z, Z). In mammalian sex determination, as well as some other insects and vertebrates, females have two of the same sex chromosomes (X, X), whereas males have two different sex chromosomes (X, Y; For review, see Adkins-Regan 2012).

Sex-determining genes present on the sex chromosomes are responsible for sex-typical development. However, even between species with the same system of sex determination, gross differences exist in the sexual differentiation process. For example, *Drosophila* (common name: fruit fly) and mammals have X, X or X, Y sex chromosomes. However, in *Drosophila* sex is determined by a balance of female determinants on the X chromosome and male determinants on the autosomes. In mammals and some other vertebrates, however, it is the presence of male-specific genes on the Y chromosome that determines the sex of the animal (For review, see Adkins-Regan 2012).

Insect sex development has primarily been thought to depend exclusively on cell-autonomous expression of sex-specific genes. By contrast, in vertebrates, sex determination is decided by the presence of the Y chromosome, from which the sex-determining region of the Y chromosome (*Sry*) triggers the development of the testes in males. In the absence of *Sry*, ovaries develop. Once gonadal development is underway in vertebrates, the hormones produced by the gonads are responsible for subsequent sexual development – a process known as sexual differentiation. The process of sexual differentiation is well conserved among vertebrate clades, although recent evidence indicates that the sexual differentiation of both vertebrates and insects rely on both sex hormones and cell-autonomous mechanisms, rather than one or the other (For review, see Bear and Monteiro 2013).

The traditional theory of sexual differentiation posits that vertebrate sexual development is dependent on hormones produced by the testes (i.e., testosterone and its metabolites, and anti-Müllerian hormone). The production of these

hormones in males stimulates the growth of male-typical external genitalia and internal reproductive structures, and inhibits the development of female-typical reproductive structures. In females, the ovaries produce very little hormones during early development; female-typical genitalia and internal reproductive structures develop in absence of the male-typical hormones. In addition to these sex differences in gross physiology, the nervous system and behavior are influenced by these hormones: Gonadal sex hormones organize the structure of the nervous system during this critical developmental period (Phoenix, Goy, Gerall & Young, 1959; for review see, Wallen 2009). These permanent changes to the nervous system allow for the potential of male- or female-typical behaviors in adulthood. During puberty and adulthood, gonadal hormones further organize and activate these sex differences, promoting male- and female-typical anatomical growth as well as sex-typical mating behaviors. Both organizational and activational hormones are required for full sex-typical sexual differentiation.

Although sexual differentiation of vertebrates is largely dependent on sex hormones (e.g., the absence of sex hormones or sex hormone receptors greatly impedes male-typical sexual differentiation of physiology as well as the brain and behavior), more recent advances have indicated a role for sex chromosomes beyond its role in gonadal development (McCarthy and Arnold 2011). For example, *Sry* has a role in the expression of dopaminergic neurons in the substantia nigra, and is thought to play a role in the 1.5-fold increase in male incidences of Parkinson's disease in humans (Dewing et al. 2006). Additionally, males are more prone to X-linked diseases: Females possess two X chromosomes, whereas males have one X chromosome and a Y chromosome. In each cell of males and females only one X chromosome is expressed. In females one of her X chromosomes is silenced via the gene *X-ist*. This process called X-inactivation compensates for the additional genetic material. If a female possesses a defect on one X-chromosome, her other X-chromosome steps in and counteracts any negative effects of the defected X-chromosome. However, because

males only have one X-chromosome, any X-linked disease will be expressed in males (For review see, McCarthy and Arnold 2011).

The role of sex chromosomes has been further delineated by advanced genetic engineering of mice. Briefly, the Four Core Genotype model allows the generation of XX genetic female mice with male gonads (i.e., testes) as well as XY genetic males with female gonads (i.e., ovaries). Comparisons between these mice and their wildtype siblings confirm the importance of hormones on sexual differentiation of the brain and behavior in mammals. However, these models have also indicated important interactions of hormones with sex chromosomes, as well as sex chromosome-independent effects on sex differences in social behaviors, aggression, parenting as well as susceptibility to neural disease (For review see, McCarthy and Arnold 2011).

In addition to the new evidence of a role for sex chromosomes in sexual differentiation of mammals, recent studies have also indicated that female sexual differentiation is not a default that occurs in absence of *Sry* and male-typical gonadal development, as originally described by the traditional theory of sexual differentiation. Similar to male differentiation, recent genetic studies suggest that two pathways simultaneously repress male-specific gene activation and activate female-specific genes in typical female sexual differentiation (Baillet et al. 2010). Furthermore, although estrogens are not synthesized by female gonads until much later in life compared to testicular hormone synthesis (e.g., 2 weeks postnatal in female mice compared to prenatal hormone synthesis in male mice), organizational effects of maternal estrogens during the early critical period of development are necessary for full female-typical neural development as well as for the full display of copulatory behaviors in adulthood (Bakker and Brock 2010).

Ultimate Development of Sex Differences

In addition to the theory of natural selection, Darwin (1871) proposed the theory of sexual selection to explain sex differences observed across species. Advantages in intrasexual competition (i.e., competition with members of the same sex

over mates) and intersexual choice (i.e., discriminative choice of mating partners) determine the reproductive success of individuals within a species. Briefly, traits that are beneficial to gaining access to and/or attract mating partners increase reproductive success, and thus are maintained throughout evolution.

The traits that are sexually selected depend on the reproductive strategy of a species. Generally, intra- and intersexual selection pressures will affect the sexes differently. As explained by parental investment theory, the reproductive strategy (i.e., discriminatory mate choice vs. promiscuity) often depends on the number of offspring each sex can produce (Trivers 1972). The sex with lower rates of reproductive ability invests more in parenting and is more selective in mate choice; intersexual competition is typically displayed by the sex with higher parental investment. Conversely, the sex with greater potential for high numbers of offspring invest less in parenting, is less selective in mate choice, and exhibit intense intrasexual competition.

In more than 95% of mammalian species, females are limited in the number of offspring they can produce; whereas males are limited only by the number of mates they can gain access to (Clutton-Brock 1989). Typically, females are restricted by the number of eggs/ova they possess, by the relatively small window of fertility, and more prominently, by the number of pregnancies they can have as a consequence of long gestational periods. In contrast, males produce sperm quickly and in large amounts, and can impregnate many partners in the same amount of time that a female can only sustain one pregnancy. Thus, females will tend to select mates carefully, and will try to find a partner with healthy genes and resources to promote the success of their limited number of offspring. Conversely, males tend to spend their efforts attempting to gain access to as many mates as possible to increase their reproductive success. Traits that favor the sexes reproductive strategy will persist, as well as sex differences result in the underlying neuroendocrine systems that maintain these behavioral differences.

Parental investment theory predicts that the greater the sex difference in mating strategies,

the more sex differences the species will exhibit. In line with this hypothesis, monogamous species, in which males and females have a single mating partner and both parents participate in parental care, display fewer sex differences than polygamous species, in which males and females have multiple mating partners and females are typically the primary caregivers (Trivers 1972). A compelling example is observed in two highly related species of voles – the monogamous prairie vole displays fewer sex differences in both brain and behavior compared to the polygamous montane vole (Shapiro et al. 1991; Wang et al. 1999).

Few species display strict monogamy and thus sex differences can be found in almost every species, including humans. Although monogamy among humans is generally the aspiration of many societies, polygynous marriage occurs in the majority of societies (~83%). Even in societies in which monogynous marriages are typical, men are likelier to reproduce with a new partner following divorce. Therefore, men have higher reproductive variance in humans, and accordingly, there is evidence of sexual selection pressures in humans.

Ethnographic and archeological data indicate that compared to women, men are overall physically larger, more muscular and display higher rates of physical aggression, evident by the history of male production and use of weapons against each other and the participation in violence and warfare (Puts 2016). Furthermore, cross-cultural investigations indicate sex differences in humans according to mating strategies predicted by parental investment theory: males tend to prefer characteristics of reproductive capacity in females (e.g., youthfulness, physical attractiveness), whereas females prefer mates with resource acquisition potential (e.g., industriousness, ambition; Buss 1989). However, female mate choice (i.e., women's ability to freely choose mates) was likely limited in ancestral societies by men's social power and force. In line with this idea, recent work suggests that male secondary sex traits are less related to female mate choice and more effective for intrasexual competition (e.g., beards and robust faces are more effective at intimidating other men rather than attracting females; Puts 2016). Finally, there is evidence of

sperm competition in humans (i.e., competition within a single female between the sperm of multiple males). Humans are intermediate between the highly polygamous macaques and the highly monogamous gorillas in terms of sperm motility, such that it can take multiple days for sperm to meet the ovum of a female (Reviewed in Puts 2016). This delay allows time for healthier, faster-swimming sperm to reach the ovum first, and is a trait found in polygamous species. Evidence suggests that humans evolved in primarily polygamous societies and were subject to sexual selection pressures, although the high variance suggests that other factors have promoted a certain degree of monogamy.

Since Trivers (1972) proposed parental investment theory, other factors that can alter mating strategy and thus sex differences have been evaluated. For example, changes in mating strategy can occur due to a skew in the sex ratios of a species population (e.g., due to biases in the sex ratio at birth or in juvenile/adult survival). Under these circumstances, sex role reversals can be found such that females can become less selective and display increased intrasexual competition when few male mating partners are available, and males can become more selective in choosing from the relatively high number of available female mating partners. Furthermore, if there are factors that create large differences in the health of one sex, mating strategies can be adjusted. For example, males can become more selective when there are large numbers of females with variation in mating quality, that is, if reproductive success is diminished to the extent that selecting superior females will increase the number of offspring (For review, see Clutton-Brock 2007).

Species that evolved in extreme environmental conditions, in which the survival of both sexes are endangered, can develop unusual mating strategies that may be accompanied by unusual displays of sex differences. For example, the *Heterocephalus glaber* (common name: the naked mole-rat) is one of a few mammalian species that have developed an extreme form of cooperative breeding, called *eusociality* (For review, see Holmes et al. 2009). One breeding female and 1–3 breeding males are the only reproductive

members of colonies that on average are composed of 60–80 animals. All other nonbreeding members in the colony are reproductively suppressed; these animals, termed subordinates, do not undergo pubertal changes, and do not make attempts at mating. Subordinate members lack sex differences in external genital morphology, body size, gonadal steroids, or sex-typical behaviors (i.e., both sexes participate in parental care, colony work, and predator defense). However, sex differences can develop in subordinates if removed from their colony and housed with an opposite-sex conspecific. While transitioning from subordinate to a reproductively capable animal, sex differences emerge in the level of sex hormones, as well as in the expression of steroid hormone receptor messenger RNA in the brain (Swift-Gallant et al. 2015). Cooperative breeding is likely necessary for this species' survival; food is challenging to locate in the subterranean burrows where the naked-mole rat resides, and during dry season the soil becomes difficult to burrow, making food retrieval especially challenging. Many colony members are required to successfully reach food sources (Holmes et al. 2009) and thus eusociality likely evolved for this adaptive advantage.

The development of complex social structures within species can also gravely influence sexual selection pressures. For example, in some species, sex-reversal developed such that females are more aggressive/competitive than males. One extreme example is the spotted hyena. In this species, the male-typical endocrine mechanisms that underlie the sexual differentiation of aggression seem to have been co-opted by females to support the display of aggression and competition for rank within their social hierarchies. Gross aberrations in the female spotted hyenas' genitalia support the idea that females are exposed to male-typical endocrine influences. Specifically, female spotted hyenas have pseudopenises that resemble the external genitalia of males. Although the exact mechanisms underlying the genital growth in females is disputed, there is evidence that androgens, such as testosterone and its metabolites, are responsible for both the display of aggression in these animals as well as the male-typical genitalia in females (Glickman et al. 2006; McFadden et al. 2006).

In many cases, traits that are seemingly counter to a species' survival and/or reproductive success develop due to sexual selection pressures. For example, in some species males offer a nuptial gift to secure a mating opportunity, which are highly costly in terms of energy and resources of the male (Gwynne 2008), and in some cases the male himself is the nuptial gift as the female cannibalizes him, terminating his future reproductive success (Bilde et al. 2006). In many other species, males have flamboyant displays (i.e., that project health/propensity for survival) to attract mates, at the cost of also catching the attention of predators (Clutton-Brock 2007) – an obvious example being the vibrantly colored male peacock. In the case of the spotted hyena, the evolution of the pseudopenis in females appears to *decrease* reproductive success – more offspring are produced by female hyenas treated prenatally with anti-androgen that produce a smaller pseudopenis (Glickman et al. 2006), and thus it appears that the increased aggression displayed by females with a pseudopenis supersedes the reproductive downfall of the male-typical external genitalia. Although many of these costs seem counterintuitive to the theory of sexual and natural selection, research indicates that these traits may have evolved to ensure reproductive success.

Together, environmental conditions, sex ratios, gestational length, and social structures all contribute to mating strategies that work best for the reproductive success of various species. Depending on the mating strategies that develop, sex differences in physical morphology and neurodevelopment evolve to support each of the sexes' mating strategy. This accounts for why sex differences across species range from large and numerous to few and small, and why in some species a trait can be more male-typical while the same trait will be more female-typical in another species.

The Functional Significance of the Magnitude of Sex Differences

Sexual dimorphism and sex differences are terms that are often used interchangeably. However, it

has been argued that a meaningful distinction should be made, and this distinction relates to the evolutionary function behind the sexual differentiation of the trait in question.

Sexual dimorphism is the term typically used when two distinct forms exist, with little overlap between the sexes (review by McCarthy et al. 2012). It can also be used when the trait is present in one but absent in the other sex. These types of sex differences are often directly associated with reproduction, i.e., courtship behaviors (e.g., male bird courtship singing) or copulatory behaviors (e.g., insertive vs. receptive; mounting vs. lordosis). Brain regions associated with sexually dimorphic behaviors are often obviously different in the number, shape, and biochemical make-up of neurons and glial cells. For example, the sexually dimorphic nucleus of the medial preoptic area (subdivision INAH3 in humans) is larger, contains more and larger neurons, and shows neural activational differences between males and females (Hendricks and Scheetz 1973; Arendash and Gorski 1983; Allen et al. 1989; Savic et al. 2001). The functions of this brain region include many basic sexual behaviors and preferences in males.

The term sex difference is often used for differences between the sexes that are not as binary. Many sex differences fall along a continuum: Males and females can land on either extreme of the continuum; however, sex differences exist in the overall averages. At the neuroanatomical level, these differences are not as distinct as sexual dimorphisms, although some sex differences are still observed in neuron/glial number and/or size, and/or neural responses. These sex differences are not always directly related to reproduction, but often result due to downstream effects of genes, hormones, and environment associated with reproductive success. For example, female humans display increased empathy on average compared to males. This sex difference in empathy has been associated with reproductive hormones such as testosterone (fetal testosterone decreases ability to empathize; for review, see Christov-Moore et al. 2014). Although empathy may not be directly linked with reproductive function or mating, it may have evolutionary

advantages; empathy, the ability to understand and share in the internal states of others, has advantages for building social relationships. Females, being the primary caregiver in many species, may have an increased benefit from the display of empathy for the purpose of understanding the needs of their offspring (Christov-Moore et al. 2014).

In addition to sex differences that likely evolved due to sexual selection, De Vries has proposed that some sex differences may exist to *compensate* for the sex differences in physiology. Sex differences in brain structure may prevent sex differences in overt functions and behavior, while in other instances no sex difference may be observable in a particular behavior, but the underlying neuroanatomy and/or neurophysiology may differ between the sexes. For example, parental care is relatively equal among the monogamous male and female prairie voles; however, differences exist in the underlying mechanisms leading to parental care in this species – hormones produced during pregnancy facilitate the display of maternal care in females, but in males a neuropeptide, vasopressin, underlies paternal care behavior (De Vries 2004).

Conclusion

Research in comparative evolutionary psychology indicates that the development of sex differences across species can largely be traced to sex-specific effects of genes and hormones. However, the sexual selection pressures on a given species determine the nature and extent of the sex differences that develop. Sex-specific genes and hormones are well conserved throughout vertebrate evolution; however, the function of these genes and hormones are co-opted to produce sex differences that contribute to the reproductive success of a species. Through the use of comparative psychology approaches and by studying the evolutionary history of species, evolutionary psychologists continue to expand our understanding of why sex differences develop as well as how the mechanisms underlying sexual differentiation evolve to allow for sexual selection.

Definition

Behaviors that develop throughout infancy and childhood, such as crawling, walking, and talking.

Introduction

As infants enter the world, their awareness and perception of their environment are experienced through their response to external stimuli. At the time of birth, infants possess functional sensory skills including audition, haptics, olfaction, gustation, and vision. These skills enable infants to obtain information and stimulation from their environment while also maturing these senses to further gain perceptual knowledge in their later years. After birth, humans continue to develop and achieve new functions as they grow. This development of a new function is considered a milestone in human development. As one grows into adulthood, he or she will undergo multiple cognitive and physical milestones, including critical developments in language/communication and motor/movement skills.

Although every individual endures his or her own unique course of development for approximately the first 15 years of life, most people experience developmental milestones at approximately the same age in their lives. Generally, delay in developmental milestones is associated with a subsequent diagnosis of learning disabilities (Murray et al. 2007). It is critical for healthcare professionals and parents to maintain close attention to the development of their children as routine developmental surveillance (both clinical clues and developmental milestones) can be signals to indicate the need for in-depth assessment which can detect possible developmental conditions (Romanczyk et al. 2005).

The Five Senses: Vision

Every individual relies on the development of his or her five senses. Every second of every day at least one of the five senses is firing; these senses are even working when one is asleep. The five senses are a fundamental component to consciousness and help one understand the world around them, collaborating to ensure the individual maintains a safe and healthy lifestyle. One's senses impact the way in which humans live by creating a major influence on the development throughout one's lifespan.

At the time of birth, an infant's visual perception is still developing but is capable of viewing objects up close. In comparison to the vision of an adult, infants are unable to see images of small diameter at a distance due to the underdeveloped muscles, lenses, and nerves (Santrock 2011). An infant's visual perception is "estimated to be 20/240 on the Snellen chart used for eye examinations, which means that a newborn can see at 20 feet what a normal adult can see at 240 feet" (Santrock 2011, p. 135). However, the lack of 20/20 vision gives them just enough visual perception for one's role as an infant. Human primates depend heavily on the sensory system with more than half of the brain dealing with the processing of visual information (Slater 1998). By approximately 6 months old, one should perceive the world with 20/40 vision. However, satisfactory vision requires coordination of sensory vision (i.e., form, motion, color, and pattern with precise eye movement) (Slater 1998). It is important for an infant to seek visual stimulation early in life. Visual development is comprised of a variety of sensitive periods for distinctive visual functions. If one is visually deprived early in life, he or she will often fail to develop full visual capabilities (Slater 1998).

One's ability to perceive light involves an interaction of mechanisms at the retina in order to perceive the wavelengths of light in the visible spectrum (Slater 1998). Specifically, it is crucial for an infant to develop the two types of photoreceptors known as *rods* and *cones*. Rods are light-sensitive cells located within the retina of the eye and allow one to see objects in dim lighting. On the other hand, cones allow one to perceive color and objects in bright lighting. There are three different cone types in the normal human: S-cones, which see short-wavelength light (e.g., blue); M-cones, which see medium-wavelength light (e.g., green); and L-cones, which see long-wavelength light (e.g., red). Failure to develop these three different cone types can result in color blindness (Slater 1998).

As a child develops, not only does he or she undergo the process of developing vision, but simultaneously developing color vision as well. The average child can distinguish between

various colors by 8 weeks old, although some evidence indicate they may be able to distinguish various colors by 4 weeks (Santrock 2011). However, other scientific evidence has indicated 1-month-olds often fail to make some color discriminations (e.g., green vs. yellow) that one would expect they should be able to make if they had all four functional photoreceptors (rods plus three cone types) (Slater 1998). However, by 2 months, evidence suggests that normal infants can make most discrimination, particularly if stimuli are large and differences between stimuli are marked.

An important development in vision is the development of perceptual constancy. Perceptual constancy allows for an infant to perceive an object as the same at different distances or different orientations. There are multiple types of perceptual constancy, including shape constancy and size constancy. Humans experience shape constancy when viewing moving objects. When an object moves, there is a change in its spatial orientation; however, when one views the moving object, these changes in the object's spatial orientation do not affect the person's visual perception of it (Slater 1998). For example, if a person views a closed door, he or she may view the door as a rectangle. However, if the door is opened, the shape of the door (from the angle of the viewer) changes to something more trapezoidal in shape, but the viewer will still see the door as its original shape (i.e., rectangular). It has been found that infants at 3 months possess shape constancy, but do not have shape constancy for irregular shaped objects (Santrock 2011).

Size constancy is the awareness of an object's size as one moves toward or away from the object. Hence, the size of an object on the retina does not tell the viewer the object's actual size (Santrock 2011). For example, as objects move farther away from a viewer, the object appears smaller, but the viewer is aware that the object has not actually changed in size. Infants display some size constancy at 3 months old, but it is not fully developed until 10 or 11 years of age (Santrock 2011).

Once an individual reached adulthood, they have perception of occluded objects, whereas during infancy, one cannot perceive an object as a

whole when it is blocked by another object in front of it. By approximately 3–5 months of age, an infant has the capability to track temporarily occluded moving objects, and around 5–9 months of age, infants have the ability to trail moving objects that disappear progressively behind an obstructed barrier, disappeared abruptly, or collapse, although an individual is more capable of predicting a moving object when it disappears gradually rather than abruptly or collapsing (Santrock 2011).

Depth perception also plays a vital role in one's life, as it allows for one to accurately recognize the location of objects in one's environment, which is essential for efficient movement within one's environment. Depth perception, also referred to as stereopsis, is "when specialize cells in the brain's visual cortex compare the inputs from the two eyes and abstract a signal that conveys very small depth differences for targets that are relatively close – within arm's length" (Slater 1998, p. 34). In a landmark study, Walk and Gibson (1960) assessed infants' depth perception by constructing a miniature cliff with a drop-off covered by glass to give the illusion of an actual cliff. As infants were placed on the edge of the visual cliff, mothers coaxed them to crawl onto the glass; however, most infants would not crawl past the shallow side onto the glass. This was an indication that infants could perceive depth from 6 to 12 months of age (Santrock 2011). However, due to the inability to crawl at a young age, it is difficult to detect whether younger infants perceive depth. An alternative study was conducted on younger infants due to the incapability of crawling. The researchers monitored the infants' heart rates to measure their ability to perceive depth. Between 2- and 4-month-old infants, there were differences found in heart rate when they were placed on the deep side of the visual cliff instead of on the shallow side (Santrock 2011). However, this was not a valid acquisition but rather a display of differences between younger and older infants' visual characteristics, with no definite knowledge of depth. It can be concluded that infants of about 3–4 months of age develop the ability to use binocular cues to depth (Santrock 2011).

The Five Senses: Audition

Humans' sense of hearing develops while in the womb. Hearing is one's ability to recognize sound by the current of vibrations entering the ear. Within the last 2 months of pregnancy, the fetus has the ability to hear sounds such as the mother's voice or music (Santrock 2011). The changes in an individual's hearing are due to the perception of a sound's loudness, pitch, and localization. At the time of birth, infants do not have the capability to hear soft sounds, so they require communication to be spoken at normal conversation level rather than soft whispers. Pitch is the perception of the frequency of a sound. Infants are less sensitive to deeper low-pitched sounds and are more likely to hear high-pitched sounds (Santrock 2011).

At 1 month old, infants begin to show interest in the sound of human voices – specifically, the voice of their parents (James 2009). By 2 months old, infants become interested in the exchange of communication between two individuals. Infants can differentiate between sounds' pitches and intensities (James 2009). Infants also have the capability to generalize the location where sound is coming from (Santrock 2011). As sound is produced, an infant will turn his/her head in the direction the sound is coming from (James 2009). At 4 months old, infants develop the ability to hear soft sounds. Around 5 months old, infants have the ability to develop his/her understanding of language (James 2009).

Six to ten months is a major stepping stone in the development of an infant's understanding of sound. As infants are able to identify certain sounds, they may imitate those sounds and/or respond to their names (James 2009). Moreover, this time frame develops an infant's ability to link words with gestures (waving goodbye and saying goodbye mean the same thing). When approaching 10 months old, an infant can identify the difference between a male voice and a female voice (James 2009). Before an infant reaches 1 year, he/she will have the capability to participate in a conversation. However, they can understand more words than they can speak (James 2009).

The Five Senses: Smell and Taste

Individual's olfactory sense allows for one to identify between different odors and be consciously aware of one's external environment. Olfactory sense also plays a key role in his or her gustation perception and can have linkage to other somatic systems (respiratory and/or neurological) (Wittmann-Price 2010). The olfactory sensory epithelium is composed of a few million olfactory sensory neurons (OSNs), which are generated in situ from stem cells (Mombaerts 2001). Facial expressions are reliable indicators of the portrayal of smell. For example, a face of disgust represents smelling something repulsive, and a face of delight represents smelling something sweet or savory. With this, one can identify if a newborn has developed an olfactory sense. The expressions on an infant's face tell one that the infant enjoys sweet smells, vanilla and strawberry, but dislike the scents of odd or foul foods such as fish or rotten eggs (Santrock 2011).

Additionally, olfactory and gustatory senses begin developing in utero, which has great implications for lifelong nutritional habits (Wittmann-Price 2010). As one begins to eat, their taste buds are highly linked with sense of smell; this is "because olfactory receptors are stimulated from both the nostrils and nasopharyngeal passages" (Wittmann-Price 2010, p. 2546). Between 8 and 9 weeks in fetal development, the taste buds begin to develop, while the olfactory system is developed between 16 and 18 weeks. By 28–29 weeks, olfactory receptor neurons are mature (Wittmann-Price 2010).

As a mother is pregnant, her diet has a key impact on the child's lifelong taste preference because of certain dietary selections (Wittmann-Price 2010). Research found that 6-day-old infants who were breastfed displayed a higher preference for smelling their mother's breast pad over one that was clean. Although once the infant was 2 days old, there was no indication of this preference suggesting that recognition of scent requires several days (Santrock 2011).

Gustation and olfactory senses are closed linked (Breslin 2013). Taste is stimulated when nutrients or other chemical compounds activate

specialized receptor cells within the oral cavity. Individuals have the capability to differentiate between the four basic tastes of sweet, sour, salty, and bitter. One's preference to taste is influenced by diet and nutrition. In order for the sense of taste to develop, papillae – taste receptors inside taste buds – must develop. Taste has a heavy influence on the body as it allows humans to evaluate food for nutrition as well as harmful toxins, allowing humans to decide what to ingest. It also helps the body prepare for the metabolizing of foods once they have been ingested (Breslin 2013).

It is important for an individual to be able to identify taste to be aware of toxins going into the body. Human taste abilities have been shaped by the ecological niches our evolutionary ancestors occupied and by the nutrients they sought (Breslin 2013). Additionally, it allows for one to properly develop by ingesting the necessary nutrients and avoiding harmful substances.

The Five Senses: Haptics

The sense of touch – known as somatosensory function – is defined as the detection, discrimination, and recognition of touch sensation and proprioception (Dunn et al. 2015). The process of sensation is conveyed by sensory receptions in the skin, joints, tendons, muscles, and viscera (Dunn et al. 2015).

Somatosensory has been measured on four levels: detection (noticing stimuli), discrimination (distinguishing among stimuli) affecting the quality of movement, scaling (grading stimuli), and object recognition (knowing what the object is by touch) (Dunn et al. 2015). Not only does somatosensory allow one to experience touch sensation and proprioception, it makes possible for one to experience pleasure and satisfaction, learn and adapt, and experience the touch of others (Dunn et al. 2015). At the time of birth, a newborn has the sensation of touch, as a touch to the newborn's cheek can result in the turn of the head and a touch to the lips initiates the rooting reflex (i.e., sucking movements) (Santrock 2011).

Children between 3 and 4 years of age display the most inconsistency and failure among detection, discrimination, scaling, and object recognition. However, accuracy improved as the child got older, which is consistent with the rate of development of the somatosensory cortex in the children's brains (Dunn et al. 2015). As one gets older (over 70 years), their haptic recognition (recognizing an object simply by touch) and sense of touch in their feet become significantly less accurate. This decline is more pronounced in aging females than males (Dunn et al. 2015). This difference is probably due to age-related changes in the nervous system.

Physical Development: Gross Motor Skills

Gross motor skills are large general movements that require development of muscle tone and involve large muscle activities. For example, controlling one's posture – the ability to sit upright and/or stand – is a gross motor skill that is foundational in the development of other gross motor skills like crawling and walking (Santrock 2011). The start of postural control starts at infancy. Within the first few weeks of life, an infant can hold their head erect and not long after can lift their heads (Santrock 2011). By 2 months old, infants have the ability to sit in an infant seat or on an adult's lap with support, and between 6 and 7 months, an infant can sit independently without support. From the development of postural control, an infant develops the ability to stand between 8 and 9 months by pulling oneself up and being supported. Between 10–12 months, an infant can stand alone (Santrock 2011). This leads into 1 year of age, the time where the development of crawling and walking beings.

Much like an individual's five senses, the development of motor skills goes through a step-by-step development over the course of one's lifespan. Arnold Gesell, a developmental psychologist, discovered that there is a fixed order and time frame where children progress between rolling, sitting, standing, and other motor skills (Santrock 2011). This structured development Gesell argued is preprogrammed by one's genes.

Conversely, later research has indicated that one's motor development is not as congruent as Gesell had claimed. Esther Thelen proposed an influential counter theory – known as dynamic systems theory – which argued that perception and action are connected, as an infant uses his/her perception in the environment to seek an object or person of interest. This motivates the infant and develops one's motor skills (Santrock 2011).

Researchers in the 1930s claimed that there were two main factors impeding achievement of walking: leg strength and balance control (Adolph et al. 2011). It is important for one to be able to gain muscle strength and maintain balance in order for an individual to develop one's motor skills. An infant needs to be able to sustain body weight and balance on one leg at a time, "prior to independent walking, infants exhibit several transient upright skills that mitigate the requirements of single limb support" (Adolph et al. 2011, p. 306). Additionally, infants need the ability to control their muscles. Infants learn to walk once maturation of the nervous system allows them to gain the ability to have this sense of control. Starting at a very young age, the neural pathways that control leg alteration are developed (Santrock 2011).

Infants look for support when learning to walk, whether it is a parent's hand or nearby furniture. At roughly 14 months old, an infant has the ability to hold onto furniture to pull up to an upright position. Also at this age, infants have the strength to stand alone, walk forward, or cruise sideways with the support from furniture (Adolph et al. 2011). Cruising is the process that infants may develop prior to crawling – it involves the infant walking in a shuffling manner while holding on to furniture. Cruising has been linked to the development of leg strength as well as increases in sensitivity to perceptual information for balance and coordination (Adolph et al. 2011).

Different milestones involved in walking happen at different times for individuals but are developed within the same age range. Most infants cannot walk until their first year of life. From birth to about 6 months, however, infants engage in kicking movements while on their back. By approximately 9 months, an infant is capable of

judging the depth in front of him or her in order to learn forward in a sitting position (Adolph et al. 2011). When learning to walk, an infant's process changes each time they attempt to walk as by walking continuously; each walking step is slightly different from the last. This is because of the different locations and grounds that one covers and the "continually varying biomechanical constraints on the body, may help infants to identify the relevant combination of strength and balance required to improve their walking skills" (Santrock 2011, p. 128).

Although the first year is a major milestone due to the development of walking, the second year of life a child becomes more comfortable and mobile. Once infants approach 1 year, the developmental process time span expands giving infants more range in which they reach various milestones. Between 18 and 24 months, children begin the process of walking quickly or a variation of running for a short distance (Santrock 2011). Additionally, during this age range, infants learn to balance on their feet while squatting to play, walking backward without losing balance, kicking a ball while standing and not falling, throwing a ball, and jumping in place. From here on, infants continue to grow and master the skills of walking, and running eventually becomes more automatic and less conscious (Santrock 2011).

Cognitive Development: Piaget's Four Stages

The development of cognitive abilities throughout childhood allows children to begin developing schemas – which are cognitive frameworks that help people organize information that they learn in a way that helps them make sense of the world (Santrock 2011). Therefore, when a child has a thought regarding a certain aspect of the world, all of the information regarding that aspect is comprised in a schema, and that allows for an understanding of that aspect of the world. For example, let us say that a child has an idea of a cat. The child's schema for "cat" contains information like "small, furry, fluffy tails, meow, and smell nice." Whenever the child interacts with something that

possesses these qualities, the child understands that he/she is interacting with a cat. This is considered a state of equilibration – in which the child's understanding of *cat* is consistent with what he/she currently perceives as *cat*. However, now let us imagine that the child interacts with a skunk for the first time. The child may initially attempt to categorize the skunk in the *cat* category because they are both small and furry and have fluffy tails, but the child quickly realizes that this new animal does not meow and does not smell nice. This new information does not fit with the child's current understanding of the world, which leads to disequilibrium – a state of confusion that the child wishes to resolve. The child then attempts to resolve through processes known as assimilation and accommodation.

Assimilation is a process through which people interpret new experiences in terms of existing schemas. For example, children may learn that a skunk is not a cat because it does not meow, and it can emit a very foul smell that cats cannot. Therefore, the child develops an understanding of what a skunk is by understanding how it is different from a cat. This assimilation can allow for a new understanding of the world, which is a new state of equilibration.

Accommodation is a process of modifying one's current schemas in order to account for new experiences in one's environment. For instance, if a child has a schema for dogs that is based on his/her experiences with very small dog breeds like Chihuahuas or Pomeranians, but sees a large dog (e.g., Great Dane, St. Bernard, etc.), the child may have to change his/her schema in order to account for the new animal. Thus, the schema of *dog* changes from "small, furry, and barks" to something like "furry, barks, and size varies."

Piaget's theory of cognitive development focuses on how children use these techniques to develop these schemas and how children utilize their environment to help understand the world around them. Piaget also posits that children are active agents in their environment who are trying to obtain knowledge about the world around them. However, this ability to think and understand the world is something that develops over time and goes through some radical changes during that

process. These changes are marked by four stages of cognitive development, with each stage containing more complex abilities than the previous one.

The first stage is known as the sensorimotor stage. This stage occurs approximately during the first 2 years of one's life. During this stage, an infant will construct an understanding of the world by coordinating his/her sensory experiences with his/her motor movements. In other words, they learn by directly interacting with their environment in very basic ways, such as listening to sounds and touching objects. This allows infants to learn which sounds are desirable (e.g., pleasant sounds, like basic musical tones) and which sounds are undesirable (e.g., loud sounds that may startle the infant, such as breaking glass or a hammer hitting a wall). This also allows infants to learn which textures are pleasant to touch (e.g., soft things such as pillows, blankets, teddy bears, etc.) and which textures are unpleasant to touch (e.g., hard surfaces such as concrete, sharp objects, etc.). This stage marks the first understanding of one's surrounding environment.

The information that infants gather during the sensorimotor stage allows them to begin developing schemas. However, the sensorimotor occurs so early in life that the cognitive processes occurring in this stage are somewhat primitive when compared to the latter stages of Piaget's theory of cognitive development. For example, according to Piaget infants in this stage tend to not have object permanence yet – which means when they stop looking at an object, that object no longer exists (Piaget 1954). However, some research has shown that infants as early as 3 months old may possess some rudimentary form of object permanence (Baillargeon 1987).

Infants' actions within the sensorimotor stage begin with physical reflexes to one's environment. These reflexes eventually develop into more controlled motor movements and sporadic imitation (in which infants imitate basic motor movements that they see), which develops into more complex forms of imitation in which infants begin imitating words and facial features that they hear and see (Piaget 1951). These basic forms of movement are illustrated in children's play. During this stage,

Piaget (1951) noted that children begin engaging in practice play. This type of play consists of repeated body movements, such as putting objects in one's mouth or playing peekaboo.

The crowning achievement of the sensorimotor stage is the development of object permanence and symbolic thought. This means that the children are able to think about things (e.g., objects, people, animals, etc.) and use language, images, and gestures to articulate their thoughts about these things (Piaget 1954). At this point, these children progress to Piaget's second stage – the preoperational stage.

The preoperational stage occurs approximately between the ages of 2 years old and 7 years old. At this point, children begin to manifest their environment through talking about their home and drawing pictures of their family (Piaget 1954). However, children in this stage still have difficulty with logical thought. Specifically, preoperational children have difficulty solving conservation and classification problems. For example, if someone were to take a glass of water and pour the water into a taller, thinner glass container, children younger than 6 or 7 years old typically do not understand that the volume of liquid has not changed (i.e., it is conserved). In the case of classification difficulties, children in this stage lack class inclusion, which is the ability to relate a whole class (e.g., furry animals) to its subclasses (e.g., dogs, cats). For instance, if a researcher gives a preoperational child a drawing of seven dogs and three cats, then asks the child "are there more dogs or more animals in this picture?" the child tends to think the correct answer is *dog*.

Play in the preoperational stage increases in complexity from the sensorimotor stage. Preoperational children will often engage in make-believe role play. They may dress up as another individual (e.g., police officer, fireman, etc.). Their newly acquired ability of symbolic thought allows them to use objects to symbolize something other than the intended function. For example, they may use a ruler or stick as a pretend sword.

Children in the preoperational stage tend to be egocentric. This means that these children have a tendency to view the world solely from their own perspective. They have difficulty recognizing other people's points of view in an environment.

The three-mountain task has been used to examine this. A child is placed at a table with a model of three plastic mountains sitting side by side on it – one with a pole on it, one with a cross on it, and one with nothing on it. The child is then asked to draw the mountains the way that he/she sees it. After that, a doll is seated at the opposite side of the table, and the child is asked to draw the mountains the way that the doll sees them. Often-times, the child draws the mountains the same way as he/she sees them and does not take into account that the doll is seeing the mountains from opposite side of the table, which would reverse the order of the three mountains (e.g., the mountain with the cross on it may be on the far left from the child's perspective, which would make it look like it is on the far right from the doll's perspective).

Once children have mastered conservation and classification – and are able to understand that people see things differently from different angles and perspectives – they move on to the concrete operations stage, which is Piaget's third stage of cognitive development (Piaget 1954). This takes place approximately between the ages of 7 years old and 11 years old.). During this stage, play develops into games with rules. In other words, play becomes more structured with rules. This may also cause the development of teams and competition (Piaget 1951). Also during this stage, children are able to understand that properties such as mass, weight, and volume do not change when an object changes form. For example, if an ice cube melts, it still contains the same amount of water. Children in this stage also tend to be successful with classifying objects by a varying number of classes (e.g., weight, size, color, etc.). However, in this stage of cognitive development, children tend to only do well with concrete examples – not abstract ones. In other words, physical examples are needed for these children to understand the concepts of conservation and classification. Trying to reason with abstract principles tends to be too difficult for children in this stage (Piaget 1954).

The fourth and final stage of Piaget's theory of cognitive development is known as the formal operations stage. This stage takes place from 11 years old to adulthood (Piaget 1954). It is in this stage where children are able to develop

rational thought regarding abstract ideas and principles – no physical examples are needed anymore. Many forms of complex thought begin to develop in the formal operations stage. For example, metacognition begins to occur. This is the ability to think about one's own thoughts. This allows for adolescents to ponder the purpose and utility of their thoughts and emotions. This helps develop self-regulatory learning, which is the ability to monitor one's own thoughts and behaviors in order to reach a specific goal. For example, John is an eighth grade student who realizes his grades have begun to decline. After thinking about it for a while, John realizes that he is easily distracted by his best friend who sits next to him in class. John likes his best friend and has a lot of fun talking to him, and that is why he sits next to him, but John has a goal of making the honor roll this year, so he has decided to sit in a different seat so that he can complete his work and improve his grades.

This complex thinking also leads to hypothetical-deductive reasoning, which is the ability to develop predictions/hypotheses and test them. This ability is often examined using the pendulum task. Adolescents are asked one question: "Which of the three things contributes to how much a pendulum swings: the weight of the pendulum, the length of the pendulum's string, or the force at which the pendulum is pushed?" The adolescents are then given three strings that vary in length and three different weights. The point of the task is to see how the participants reason through it. People who are not engaging in hypothetical-deductive reasoning tend to grab strings and weights at random, whereas those who are engaging in hypothetical-deductive reasoning tend to grab one weight, then systematically vary the string length, and vary the force at which they push the pendulum in order to see if variations in length or force affect the swing of the pendulum (Siegler et al. 1973).

Cognitive Development: Attention and Memory

Cognitive functioning is an important development process for an individual as it is the makeup

of memory, attention, and reasoning to develop one's knowledge. Attention is defined as the focusing of mental resources on select information (Santrock 2011). Attention allows one to fixate on a task or object and not get distracted. One's attention process determines the information selected for subsequent perception, action, learning, and memory (Amso and Scerif 2015).

During infancy one's visual attention is strongly influenced by eye movements. At 3 months old, when pointed to by a parent, infants can rapidly change his/her visual attention, but it is not until between 4 and 6 months old that an infant can suppress competing information during attention-orienting shifts (Amso and Scerif 2015). This involves being able to direct attention to important locations and object features such as color and/or shape (Santrock 2011).

Another type of attention is called *sustained attention* or *focused attention* which allows infants to learn and remember attributes of a stimulus as it becomes familiar (Santrock 2011). Sustained attention can be found within infants as young as 3 months old and develops substantially in the second year of life (Santrock 2011).

At approximately 7 to 8 months old, an infant develops another aspect of attention known as *joint attention*. Joint attention is the process of focusing on the same object or event, which requires the ability to track another's behavior (e.g., following someone's gaze), directing the behavior of another, and common interactions (Santrock 2011). Then, by an infant's first year of life, he/she has the capability to direct adults' attention to objects or images that grasp their concentration (Santrock 2011). Attention in an individual continues to develop throughout childhood and improves significantly within the preschool years.

There are two areas of attention that children develop during the preschool years: *executive attention* and *sustained attention*. Executive attention includes goal-directed behavior that allows the child to pay attention to goals, planning, and even errors that impede goal achievement. Executive attention is also utilized to help the child understand how to deal with difficult situations. Sustained attention, on the other hand, allows for

extended focus on particular objects, events, or other aspects of one's environment (Santrock 2011). During the preschool years, the more a stimulus stands out in their environment, the more attention children will pay attention to it. When an infant or child has the inability to fixate on an object or task, it could be the result of atypical visual attention development. Atypical visual attention development is an abnormal attention span which can be indicative of a variety of disorders including attention deficit hyperactivity disorder (ADHD), autism spectrum disorder (ASD), and/or fragile X syndrome (FXS) (Amso and Scerif 2015). One's attention correlates highly with working memory capacity and his/her short-term and long-term memory.

Infants between 2 and 6 months old have the capability to remember certain experiences through 2 years of age. However, this can be the cause of infants only using implicit memory rather than both implicit and explicit memory according (Santrock 2011). Implicit memory is memory without conscious recollection, such as procedural memory – memories of skills and routine procedures that are preformed automatically. Explicit memory, on the other hand, is memory that requires conscious attention, such as the memory of facts (semantic memory) and experiences (episodic memory). In infancy, one's explicit memory of brief experienced visual information can be stored for up to 2 weeks (Schneider and Ornstein 2015). A longitudinal study of infants within their second year of life found that “older infants showed more accurate memory and required fewer prompts to demonstrate their memory than younger infants” (Santrock 2011, p. 158). Researchers have acknowledged that 6-month-old infants have a better ability of remembering information for 24 h. Infants by the age of 20 months have the ability to remember information they encountered 12 months earlier (Santrock 2011).

When given enough exposure and appropriate cues, infants can retrieve information after extended periods of time. This retention increases linearly between 2 and 18 months of age (Schneider and Ornstein 2015). However, most individuals cannot remember any events that occurred prior to the age of 3–5 years old. This

memory loss, known as *infantile amnesia*, is caused by the lack of a fully developed prefrontal cortex and hippocampus (the so-called memory center of the brain) during these early years of life (Santrock 2011). Therefore, during individual's younger years, their memory is rather brief and requires time and development to become substantial.

Cognitive Development: Language and Communication

Language is a way for individuals to communicate with others, which can manifest verbally or visually (in the form of writing or images). The community one lives in defines both written and spoken languages. The variation of dialect the community uses also affects the way written language is utilized. The use of language is important in one's life because individuals utilize language to share and/or exchange information, news, and ideas.

All languages are comprised of phonological development. Phonology is the study of sound systems – specifically how sounds are used and combined – referring to the system of a distinct language (Stoel-Gammon 2006). At birth, infants have their own way of communicating through babbling, crying, smiles, and gestures (Renzi et al. 2017). Language development begins with the recognition of different sounds. For an infant to develop speech, they must effectively monitor and assess their own self-generated speech (Masapollo et al. 2016).

Infants are able to identify the differences in sounds in multiple languages only during the initial months of life. By 6 months old, infants become more successful at detecting the sounds and changes in the language their parents or guardians speak to them. As an infant reaches 5 months old, they have the ability to vastly develop their vocal skills by viewing an adult pronouncing vowels and sounds on a television (Masapollo et al. 2016). Infants have the ability to link sensory patterns with what they see and hear with sensorimotor patterns that they are trying to construct. Infants pay close attention to

phonological features, which allows infants to recognize permissible sequences of these phonological features as well as their frequency of occurrence within the language input the infants receive (Stoel-Gammon 2006). The input that infants often retain and learn language through differs from that of “normal speech.” Infant-directed speech is also known as “motherese,” characterized by reduced speed, elevated pitch and affect, and unusual prosody (Eaves et al. 2016).

The first 3 years consists of “prelinguistic” vocabulary (Stoel-Gammon 2006), which includes variations of sounds that are not actual words but resemble actual speech. For example, variations of “mama” and “dada” are not actual words yet they resemble the attempts to produce the words “mommy” and “daddy”; however, it illustrates that the infant has sound-meaning relationships of conventional adult-based words (Stoel-Gammon 2006). An infant's prelinguistic vocabulary is a production of speech containing some of the phonetic features found in adult languages, which then progresses through developmental stages. This progression begins with vowel-like utterances at 2 months old and continues through a period of vocal play toward sequential productions of consonant-vowel strings around the end of the first year (Stoel-Gammon 2006).

Linguistic development can be divided into five stages (Stoel-Gammon 2006). Stage one – known as *phonation* – takes place during the first 2 months of life. This first stage consists of verbal pronunciations that have little resemblance to adult speech due to involuntary motor patterns. Vocal behaviors during this stage involve mostly reflexive (sometimes called *vegetative*) dialogues, such as crying, fusing, coughing, sneezing, and burping.

Stage two – *cooing* – takes place between the ages of 2 and 4 months (Stoel-Gammon 2006). Intentional communication begins during this stage via expressive vocalizations and smiles. As infants become familiar with their capabilities as a communicator, they become more mindful of their parents' behaviors and the impact the infant can have on those behaviors (Renzi et al. 2017).

This stage is the production of vowel-like sounds called *coos* and “are characterized by nasal resonance and are generally perceived as containing vowels and consonants produced at the back of the mouth (velars, uvulars) and back vowels” (Stoel-Gammon 2006, p. 643). As an infant attempts to pronounce consonant-vowel syllables in stage two, he or she may struggle with timing of opening and closure gestures that are within syllable timing in adult communication (Stoel-Gammon 2006).

The third stage – known as *vocal play* – takes place during the ages of 4–6 months. During this stage, infants begin producing nonsensical vowel-like sounds such as shouting, squealing, rumbles, and raspberry sounds. Producing these sounds suggests that the infant is exploring their vocal capabilities and producing consonant-vowel syllables. Additionally, the earliest an individual can recognize their name when spoken is at 5 months.

From the ages of 6 to 10 months is considered stage four – *canonical babble*. This is the alternation of consonants and vowels. The infant’s syllables consist of single syllables or repeated syllables, such as “mama.” This is due to the “timing and phonetic characteristics of these syllables which are similar to those of adult speech” (Stoel-Gammon 2006, p. 644) and resemble words of the adult language. This is vocal progression of multisyllabic utterances and reduplicated babbles (the string of identical syllables) as well as variegated babbles (syllable strings with varying consonants and vowels). Both utterances occur in stage four (Stoel-Gammon 2006); however, variegated babble increases after the infant reaches 9–10 months (Stoel-Gammon 2006). Within approximately 8–12 months, an infant understands basic linguistics and begins using gestures to communicate. Gestures may include waving to say “goodbye,” nodding to say “yes,” and pointing to an object to acquire it or to draw attention to it.

The fifth and final stage begins at 10 months and older. This stage – known as *jargon babble* – is the stage of babble, also referred to as *intonated babble*, that is “characterized by strings of sounds and syllables uttered with a variety of stress and

intonational patterns” (Stoel-Gammon 2006, p. 644). During this stage, infants begin to use their own language instead of that of older children and adults in their environment. By 13 months old, they understand approximately 50 words. However, they cannot pronounce this many words until 18 months. Therefore an infants’ *receptive vocabulary* – the number of words they can understand – exceeds one’s spoken vocabulary (Santrock 2011).

Research on American children has found that the first words infants can recite have not changed for at least 50 years. These first words tend to be *dada, kitty, car, ball, milk, eye, hat, clock, and bye* (Stoel-Gammon 2006). By the age of 2 years old, infants’ can speak approximately 200 words. This dramatic increase in the number of words they can speak is known as a *vocabulary spurt* (Stoel-Gammon 2006). This also includes attempts of two-word speeches; therefore, a child learning the English language can produce multiple-word sentences.

Conclusion

Individuals experience a variety of changes over their lifespan that involve development in all areas and aspects. Proper development ensures individuals a healthy and proactive lifestyle that will later determine the adult he/she will become. It is important to monitor an infant and child’s development to understand if one meets the proper milestones at the given age, as there are extensive changes between birth and adolescence. Failure to reach these milestones can result in permanent underlying developmental dysfunction later in life.

Synonyms

[Diabetes mellitus](#); [DM](#)

Definition

Diabetes is a group of metabolic disorders that are characterized by high blood sugar levels over an extended amount of time.

Introduction

Within the realm of evolutionary medicine, diabetes is often thought of as a form of maladaptation to the conditions of modern society. This modern ailment is often considered to be a prime example of an evolutionary mismatch.

The Evolutionary Relevance of Diabetes

In modern society, there are three major types of diabetes, type 1, type 2, and gestational diabetes. Type 1 diabetes is characterized by the pancreases' inability to produce insulin due to different potential issues regarding beta cells. Type 2 diabetes is hallmarked by insulin resistance; the cells in the body are failing to properly react to the presence of insulin. Lastly, gestational diabetes can be found uncommonly in pregnant women with no prior history of high blood sugar levels. This type of diabetes typically resolves after the conclusion of the pregnancy.

Diabetes is often considered an evolutionary maladaptation for several reasons. For example, in ancestral conditions, coming across foods with high sugar content was exceedingly rare, with the primary source being different fruits. The consumption of foods high in sugar had huge benefits, such as increased energy, which could potentially lead to the production of additional resources. This, in turn, would help the individual survive and pass their genes onto the next generation. However, after the industrialization of society, foods high in sugar are very common and easy to purchase and consume. This leads to the problem that is the overconsumption of sugary foods, which is one of the factors that directly correlates to the development of type 2 diabetes (Lean and Morenga 2016). The overconsumption of sugary foods paired with a largely sedentary lifestyle has given rise to the modern medical problem that is type 2 diabetes. The treatment for this form of diabetes consists of dietary restrictions and an increase in exercise.

Further, research into the evolutionary background of type 1 diabetes has shed new insights onto this form of the disease. Researchers Moalem et al. state "Recent animal research has uncovered

the importance of the generation of elevated levels of glucose, glycerol and other sugar derivatives as a physiological means for cold adaptation. High concentrations of these substances depress the freezing point of body fluids and prevent the formation of ice crystals in cells through supercooling, thus acting as a cryoprotectant or antifreeze for vital organs as well as in their muscle tissue. In this paper, we hypothesize that factors predisposing to elevated levels of glucose, glycerol and other sugar derivatives may have been selected for, in part, as adaptive measures in exceedingly cold climates” (Moalem et al. 2005). This finding would suggest some evolutionary advantage to the development of type 1 diabetes, particularly for those that lived in the extreme cold, as it would have temporarily aided in survival.

Conclusion

In conclusion, diabetes is a serious medical issue within the developed, industrialized world. This disease is best considered to be a classic example of evolutionary mismatch within the realm of evolutionary medicine.

Diane Ruble

Carol Lynn Martin

Arizona State University, Tempe, AZ, USA

Introduction

Diane Nelesen Ruble is a social developmental psychologist who has contributed innovative research and theorizing across a broad array of topics relevant to evolutionary psychologists. This chapter begins with a description of her background and training, then an overview of her research interests and theoretical contributions, and ends with a brief conclusion about the contributions to the field of psychology.

Background and Training

Dr. Ruble was raised in Phoenix, Arizona, by a sports-loving family consisting of a mother, father, and three daughters. She excelled in academics as well as in sports, and those talents were apparent in her undergraduate time at Stanford University. Stanford provided the training and classes that set Dr. Ruble on her path of interest in social and developmental issues. In one of these classes with Eleanor Maccoby, her interest in gender was first peaked. She also was successful in sports being a member of the Stanford tennis team. In 1967, she graduated with honors and received a B.A. in Psychology. She then moved to University of California, Los Angeles, and was awarded a Ph.D. in Psychology in 1973.

Dr. Ruble's first academic position was at Princeton University but spent much of her

career in the Psychology Department at New York University where she was promoted to Associate and then Full Professor. Prior to settling in at NYU, she also spent a year at the University of Toronto, several years at Indiana University, and a year at University of California, San Diego. Each of these universities provided unique experiences with colleagues from social and developmental psychology, and these experiences colored Dr. Ruble's research and thinking about how children develop.

Dr. Ruble's research and theorizing led to her being asked to be Associate Editor of *Personality and Social Psychology Bulletin* and to act as Consulting Editor for the top journals in developmental (e.g., *Child Development*, *Developmental Psychology*), social psychology (*Journal of Personality and Social Psychology*, *Journal of Personality*), and women's studies (*Psychology of Women Quarterly*). Furthermore, Dr. Ruble was involved in committees for the major psychological associations including APA, APS, SRCD, and SESP. As a successful grant recipient at NIMH, she was also asked to serve on the Behavioral Science Panel for 3 years and was involved in a committee associated with NSF. Two working groups played an important role in connecting her with like-minded colleagues who were able to provide important direction for the field: one involved a Working Group on Social Identity (funded by MacArthur Foundation and Russell Sage Foundation) and the other was the MacArthur Foundation Network on Pathways through Middle Childhood.

Federal grants supported the research that Dr. Ruble conducted with a large cohort of successful graduate students. She received funding from NIMH, NIH, NSF, Spencer Foundation, Health and Welfare Canada, USA-Israel Binational Science Foundation, MacArthur Foundation, and Russell Sage Foundation. In addition to R01s from NIH/NIMH, the value of her research was acknowledged with NIMH Research Scientist Development K Awards (1984–1993), Research Scientist Award, and NIMH Merit Award.

Research and Theorizing

Two early themes marked Dr. Ruble's research, and both of these themes were carried throughout her career: gender roles/gender-related attitudes (e.g., Ruble and Higgins 1976) and understanding how children learn to use social categories and make social comparisons (e.g., Ruble et al. 1976).

Little was known about how children use social categories or other individuating information to make social comparisons prior to Dr. Ruble's research on this important issue (e.g., Rholes and Ruble 1984). Many social psychologists have been interested in the study of people's connections to and mental representations of social categories and their consequences for intergroup relations, personal choices, and well-being. It is well documented how identification with a particular social category can promote a sense of belonging and connectedness while also sometimes leading to feeling stigmatized when one's group is devalued by others. However, despite the wide-ranging importance of social category beliefs and group belongingness, until Dr. Ruble's research, little was known about when and how they develop and become linked to individual motivations and behaviors (Cameron et al. 2001; Feldman and Ruble 1977). This theme of being interested in the acquisition of such social knowledge and its implications for children's identity development trajectories and behaviors (Ruble et al. 1988) continued throughout her research career and played out in interest in social identities as well as in exploring the emergence and consequences of being a typical or atypical member of two influential social categories of race/ethnicity and gender (e.g., Rogers et al. 2012; Halim et al. 2011, 2014). Her work applying a social cognitive approach has facilitated a broader conceptualization of the nature and consequences of social identity development.

Interest in issues of how individuals change as they adopt new identities was also central to Dr. Ruble's body of research. Based on her research on this topic, she developed a phase model of transitions that accounts for the cognitive and motivational consequences that accrue with any type of social, occupational, or role

change (Ruble 1994). The phase model has been successfully applied to provide better understanding of the transitions involved in becoming a mother, taking on new occupations, and fluctuations in rigidity and flexibility in children's gender development (Trautner et al. 2005) among many other topics.

Dr. Ruble's interest in gender has been wide-ranging. She has explored a number of diverse topics as well as conducted in-depth explorations into specific gender-related topics. For instance, the range of gender-related topics she has covered and ages involved include how toddlers learn to label gender and its consequences (Zosuls et al. 2009), the development of gender concepts in children (e.g., Martin et al. 2002; Ruble et al. 2007), the development of gender stereotypes and attitudes in children and adults (e.g., Halim et al. 2012), menstrual experiences and attitudes in adolescents, and transition to motherhood (Hackel and Ruble 1992). Not surprisingly, given this range of interests, her studies include toddlers, children, and adults. Notably, one of her articles on menstrual attitudes was published in the very prestigious journal, *Science* (Ruble 1977). Although these research topics and target populations seem diverse, the questions and issues were directed by social identity theories and from cognitive/constructivist theories of gender development. Turning her social psychological lens that is informed by knowledge of significant social processes on questions of developmental importance such as the origins and trajectories of change illustrates the best of how research combining these two fields of study can inform one another, to the benefit of both.

Conclusion

Few psychologists have explored with such success the boundaries of social and developmental psychology as has Dr. Diane Ruble. Her social cognitive theoretical perspective has richly enhanced how social identities are conceptualized in the field and has broadened their investigation to include trajectories of change and transitions. Her research has illuminated the nature of and

consequences associated with being typical or atypical members of a group as well as exploring different variations in identification with social identities for children and adults. These themes and contributions relate to tenets of evolutionary psychology that cognitive processes are important in how individuals view others and ultimately how they navigate the social world.

Diet

Mariana Costa Biermann and

Mariana Gonçalves Farias

Federal University of Ceará, Fortaleza, CE, Brazil

Synonyms

Dietary; Fare; Food selection

Definition

The usual food and drink consumed by an organism or a group.

Introduction

Human diet is important for human survival, due to the need of food and water to stay alive by getting the necessary amount of calories and nutrients to maintain the organism's functions. Thus, the capacity to discriminate what can be ingested from what need to be avoided was beneficial over evolutionary time; those who fail to discriminate what is edible can get poisoned, for example, or be killed trying to capture the food intended (Tooby and DeVore 1987). Modern humans have very little obstacles to acquire food with adequate nutrients and food free of toxins. Over human evolutionary history, that wasn't so easy. Our ancestors devoted energy and time into food acquisition, recognizing whether a food was harmless, and then capturing, collecting, consuming, and digesting it (Buss 2015).

Food selection, sharing, and consumption in humans are major social activities (Rozin and Todd 2015). For example, sharing resources, such as food, may serve as a courtship and mating

strategy (Buss 2015). There are several hypotheses regarding whether and how the evolution of food preference, acquisition, sharing, and consumption in humans ancestrally promoted health and helped securing social bonds.

The Hunting Hypothesis

Securing food is an important feature of human evolution. For example, the hunting hypothesis states that large game hunting was fundamental to securing food (Tooby and DeVore 1987). This hypothesis states that humans face a unique challenge to obtain the adequate amount of nutrients from an exclusive vegetarian diet. Therefore, meat consumption would take a central feature in human groups for thousands of generations, corroborating previous research indicating that humans ingest more meat than all other primate species (Tooby and DeVore 1987). Some consequences of this specific method of food acquisition include improvement of tool making and use, the expansion of human brain, and the development of language skills for the communication necessary for cooperative activities (e.g., hunts).

The hunting hypothesis is associated to the intense parental investment in humans (i.e., provisioning hypothesis). For example, high male investments among mammals are related almost exclusively to a carnivorousness diet (Tooby and DeVore 1987). Therefore, the preference for meat consumption may also be explained by the provisioning hypothesis: the benefits of high-calorie food ingestion reflect on the efficiency to provide food for the offspring, reducing the odds of energy shortages.

The Gathering Hypothesis

The gathering hypothesis also provides a possible explanation for the evolutionary history of human eating habits (Buss 2015). This view suggests that the tools observed on the emergence of modern human were not initially for hunting but for a more secure and economical way of digging and gathering food (e.g., plants, seed, and fruits).

Evidences that the diet of human primate relatives was mainly of plants provide support to the gathering hypothesis (Buss 2015). In addition, most of the diet of modern hunter-gatherers consists of gathered plant food (Marlow 2005).

The Scavenging Hypothesis

Another hypothesis adds to the understanding of human eating habits: the scavenging hypothesis. This hypothesis states that our ancestors engaged in scavenging behaviors, that is, they seized the food remains of other predators as a method for food acquisition (Dominguez-Rodrigo et al. 2014). This method would secure the high-calorie diet but with far less energy cost. This form of food acquisition incurs a cost: meat left for some time can proliferate harmful microorganisms and quickly rot. The costs associated with eating rotten food therefore selected for psychological mechanisms in humans that motivated efforts to develop an important technique in human evolution: cooking (Tooby and DeVore 1987).

Cooking

Cooking is a technique that increases the possibilities of food manipulation. For example, cooking optimizes the digestive process because it is easier to digest cooked (vs. raw) food. Humans are the only animal species that cook or manufacture their food (Krebs 2009).

This technique improves the digestibility of the food, by increasing the absorption of nutrients and reducing the energetic cost of this process (Carmody and Wrangham 2009). This method can also help to solve the pathological consequences of toxic substances that may be found, for example, in some roots and in rot meat from scavenged remains (Carmody and Wrangham 2009).

Food Preferences

Although food preference may be influenced by individual differences, social norms, and cultural contexts, food preference is mostly shaped by

evolution (Buss 2015). Although individuals may respond differently to similar types of food (e.g., some like vegetables, and some do not), some preferences remain stable throughout human evolutionary history (e.g., preference for sweet foods). The preference for food that provides greater protection against energy shortages, while reducing the likelihood of choice for potentially hazardous foods (Starratt 2016), solved the adaptive problem of low food availability.

Several factors may affect human preference for food and include food's nutrition content and the energy cost associated to its acquisition (Rozin and Todd 2015). One important factor that affects human preference for food is palatability. Humans evolved five senses of taste: sweet, sour, salt, bitter, and umami. These senses are important for adequate consumption of essential nutrients for human survival, and it also helps to avoid toxic and rotten food (Krebs 2009).

Despite the diversity of food available, individuals maintained a preference for sweet and fatty foods. It is possible to think that natural selection operated in favor of individuals who had a preference for high-calorie foods, as these kinds of food allow longer between-meal intervals and greater energy supplies, which are specially advantageous in restricted food environments (Starratt 2016). Additionally, a preference for sweet food may be associated with the identification of ripe fruits, which is advantageous, because ripe (relative to non-ripe) fruits are more calorie dense. Moreover, human and nonhuman milk is fatty and sweet (e.g., rats, nonhuman primates), suggesting that a preference for a sweet and fat diet may be an evolved trait (Rozin and Todd 2015).

The preference for a sweet and fatty diet and the mismatch in the energy expenditure associated with food acquisition in the hunter-gatherer and modern environments have led to the emergence of obesity (Rozin and Todd 2015).

Moreover, salt is essential for the body to function properly. Because individuals lose a large amount of salt through sweat, it is advantageous for humans to prefer salty (over non-salted) food (Breslin 2013). However, similar to sweet and fatty food preference, a predisposition to choose salty (over non-salty) foods present current risks

to the modern human health. The overconsumption of salt has caused serious chronic diseases (e.g., hypertension).

Humans also presented a predilection to sour taste. Bitterness may serve as a proxy to high concentrations of vitamin C, an essential vitamin that has a great nutritional value (Breslin 2013). In addition, sour tastes are markers of fermentation, and the combination of sweet and sour tastes was more efficient for the identification of ripe fruits.

Moreover, humans can taste umami, which is associated with the presence of amino acids and ribonucleotides (Rozin and Todd 2015). Umami taste is an indicator of easily digested nutrients, pointing out to a preference for fermented foods, including cooked meats (Breslin 2013). A preference for fermented foods therefore improves and facilitates access to nutrients and probiotic bacteria.

On the other hand, alcohol, coffee, and some vegetables are examples of bitter foods. The fondness for bitter foods represents a controversial preference, once there is an innate avoidance of bitterness, due to the association with high levels of toxins such as cyanide (Rozin and Todd 2015). Another example of food that humans supposed to be averse is spicy food. However, these elements have some nutritional benefits – spices, for example, tend to hold antioxidation and antibacterial properties (Krebs 2009).

Another essential source of nutrition in mammals is milk, which has lactose as the major component. Humans need the enzyme lactase to properly absorb lactose. Most humans become lactose intolerant after weaning; some humans, however, continue to produce lactase during adulthood. It is possible that continued production of lactase during adulthood was particularly beneficial after the emergence of agriculture and livestock (Krebs 2009).

Indeed the percentage of individuals who continue to produce the enzyme lactase varies between geographical areas (Ingram et al. 2009). This variation may be due to the intense selective pressure under communities with pastoralist nomadic habits (Ingram et al. 2009). In contrast, even though the lactase persistent phenotype can represent an evolutionary advantage, the

environmental pressures for absorbing lactose were not so strong that groups of humans that were not in a context with this specific selective pressure continued to be lactose intolerant, such as most modern humans and their primate relatives (Rozin and Todd 2015).

Conclusion

The evolutionary history of the development of eating habits has a direct effect on humans. Over human evolutionary time, food preference evolved to optimize cost-benefits trade-offs of specific food ingestion (e.g., ripe vs. rotten), energetic content (e.g., high vs. low calorie), amount of available resources, as well as environmental and cultural pressures (e.g., availability of sweet foods). These elements allowed the development of specific food preferences that helped humans to behave more efficiently in regard to food selection and consumption. The diet of an organism is intrinsically linked with its survival. Moreover, a successful acquisition of food requires the ability to avoid deadly threats (e.g., harmful toxins) and recognize adequate food with the necessary nutrients (e.g., ripe fruits, fresh meat). Food acquisition also facilitates the development of social bonds (e.g., cooperation in hunting), helping humans to overcome the hostile pressures of nature.

Different Functions of Memory

Marios Constantinou
Department of Social Sciences, School of
Humanities and Social Sciences, Nicosia, Cyprus

Synonyms

Declarative memory; Encoding; Episodic memory; Implicit memory; Learning; Localization of memory substrates; Multiple memory systems

Definition

Memory, as an information processing system, encodes (function 1), stores (function 2), and retrieves learned information (function 3).

Introduction

Our memory has three major functions. It (1) encodes new information through our five senses, (2) stores information in the short-term (minutes) or long-term (hours to years) memory systems, and (3) retrieves that information when the need arises (McDermott and Roediger 2016;

Melton 1963). These three memory functions are visited in this order below.

Encoding

“Encoding refers to the initial experience of perceiving and learning information” (McDermott and Roediger 2016). In our everyday lives, we come across stimuli/information that we are already quite familiar with them and stimuli that could be either just familiar, at varying degrees, or completely unfamiliar to us. New stimuli or information that come across, in our environment, and catch our attention will be **encoded** in our memory systems and be associated with older information or concepts or upgrade these already existing cognitive concepts. For example, seeing for the first time a new model of a well-known car brand is encoded as information that is associated with the style and look of this car brand, which is already in store. Alternatively, new information or concepts may not associate with older knowledge and create novel concepts and memories, which are not related to what we already have in store (Hunt 2003); this is called distinctiveness. For example, seeing a new car model from an unknown brand, with which you never came across, will be encoded as brand new car-related information.

Encoding could take at least three forms:

- (a) Semantic Encoding, where we encode words and sentences
- (b) Visual Encoding, where we encode visual spatial information
- (c) Auditory Encoding, where we encode sounds, voices, songs
- (d) Haptic Encoding, where we encode touch sensations
- (e) Olfactory Encoding, where we encode smells and tastes

Therefore, encoding is mainly the sensory input (of information) into our memory system.

Storage

Encoded information will move into storage, which is the next level within the memory system (Smith 2014). Retaining and storing information, which was previously encoded, is a process that is reinforced or hindered by our emotional state during encoding, our emotional attachment to the information being encoded, the environment where encoding took place, the competing information present during the encoding of information, and many other internal (related to the person) and/or external (environmental) factors.

Newly encoded information could be lost if deemed irrelevant by us or if any of the aforementioned internal and/or external factors interfere during encoding or immediately after encoding. If the information is not lost, then it moves onto the next levels of processing.

There are three empirically identified stages that the encoded information could follow if not lost:

1. As the information is encoded through our senses, it makes first impressions and registers very briefly to our sensory memory (very short-term memory). Sensory memory has a very short duration of less than a second.
2. If we pay attention and concentrate on this new input of sensations then we could move this newly encoded information into our short-term memory systems. Our selective attention will select the sensory memories that are important enough to be registered into our short-term memory system. The duration of short-term memories is a matter of dispute among scientists, and it is said that they could last from seconds and minutes to hours.
3. If the information is rehearsed, reencountered, or it is important for us, then the information could move into our long-term memory system, where the process of information decay is harder to happen. Long-term memories could last for hours, years, or our entire lives. Our long-term memory is divided into explicit (includes episodic and semantic memories)

and implicit memories (included procedural and emotional memories).

Retrieval

“Retrieval is the use of learned information, induced by sensory or internal cues” (Ben-Yakov et al. 2015). The retrieval of information from our short-term memory or long-term memory systems could be rather automatic (e.g., easy to remember information, such as the name of your mother) and called **recall**. In recalling, there is no need for cues to retrieve information. Retrieval is also automatic when we recognize information that we previously learned or encountered (e.g., in a multiple-choice question or when we run across a person only for second time and recognize them). This retrieval process is called **recognition**. Both of these retrieval processes require little cognitive effort.

On the other hand, the retrieval of information could involve varying degrees of cognitive effort and called effortful recall. For example, it is probably hard to remember the name of a person you met once, a month ago, but it is even harder to remember the name of a person that you met a year ago. In both instances, you may have to remember first the location, the date, and other details before the name of the person “pops up” from your memory storage (if it ever does).

A third form of retrieval is called relearning and it involves learning information much faster when you re-encounter the same information. For example, if you memorize all of the definitions in this encyclopedia entry for a test and remember them for next week’s test, the definitions may decay if you never use these definitions again for the years to come. Later in life, however, you may reencounter and relearn this information when you are starting a new Masters Degree in Cognitive Psychology and find out that you can memorize the material faster now.

Conclusion

Encoding information through one of our senses (smell, touch, vision, hearing, or taste) leads to storing that information either for less than a second (sensory memory) or for a short period of time lasting a few minutes to a few hours (short-term memory). Long-term memories are formed if the information is rehearsed, reencountered, or it is important enough for us (e.g., emotional attachment to a piece of information). Long-term memories are then retrieved either automatically, without much cognitive effort (e.g., the name of your dog) or with varying degrees of cognitive effort (e.g., the directions to a place that you have not visited for a long time).

Definition

Differences in minimum obligatory parental investment contributed by men and women lead the sexes to diverge in their sexual strategies and affective experiences, although under certain conditions, men's mating preferences converge with women's.

Introduction

A general principle underlying mate choice is that the greater the amount of parental investment required for offspring survival, the more stringent criteria will be for potential mates (Trivers 1972). This chapter first describes necessary or obligatory parental investment, examines the origins of sex differences in obligatory parental investment, describes examples of such differences across a range of species, and highlights the consequences of these differences in terms of human sexual strategies, conflicts, and affective experiences. This chapter next describes nonobligatory parental investment that can also be beneficial for offspring survival and the implications of male parental investment in humans.

Parental Investment

Parental investment refers to any expenditure, such as time, energy, or resources, from a parent

that benefits its offspring's fitness at the expense of the parent investing the resources in other fitness components, such as the parent's own survival or mating opportunities (Trivers 1972). Parenting, in the form of provisioning and offering protection from predators and conspecifics (i.e., member of the same species), is generally associated with lower offspring mortality (Clutton-Brock 1991). As a result, offspring have a higher chance of growing into healthier adults and are better able to compete for mates who in turn produce viable offspring themselves. Thus, in species where offspring that receive parental investments are significantly more likely to survive and reproduce, evolution shaped parents who pay the cost of investing in offspring such that net-positive genetic benefits accrue to the parents.

Obligatory parental investment more specifically refers to parental investment that is *required* for offspring to be produced and survive (Geary 2005). In mammals, for instance, offspring can only be produced through a process of internal gestation in the mother, and the offspring's early nutritional and developmental needs are also vitally dependent on milk produced by the mother after birth. Pregnancies and postpartum suckling therefore represent forms of obligatory investment by mammalian females to produce and develop offspring. On the other hand, while mammalian males can provide significant parental investments (e.g., Clutton-Brock 1991), their obligatory investment consists minimally of their sperm and a few minutes for copulation; any additional paternal investment is considered a luxury rather than a necessity.

Differences in Obligatory Parental Investment

The relative contribution that male and female parents make to offspring care varies by species. In amphibians, male-only and female-only parental investments express themselves fairly equally, while biparental investment is less common. Among reptiles that exhibit parental investment, either only the female or both parents provide the investment. The majority of bird species

demonstrate biparental investment, but on average, females invest more heavily than males. In invertebrate species with parental care, the majority have female-only investment and biparental investment is uncommon. In arthropods, male parental investment exists only in eight independent lineages which constitutes a small minority. Finally, among mammals, male-only investment is completely absent, and females raise and nurture offspring alone in more than 90% of species (Clutton-Brock 1991).

Although the forms of parental investment that are required for offspring production and survival manifest differently across various sexually reproducing lifeforms, females of most species tend to demonstrate relatively greater obligatory parental investment than males. For example, in mammals, offspring's fitness is crucially dependent on internal gestation and postpartum suckling by the mother. These physiological requirements of females but not males constitute the significantly greater female obligatory parental investment and care relative to males in mammals (Trivers 1972; Clutton-Brock 1991). Humans follow this general pattern of sex differences in mammalian obligatory parental investment – women's minimum obligatory parental investment includes approximately 9 months of pregnancy and is often followed up with years of nurturance in the child during his or her formative years. In comparison, men's minimum obligatory investment is a single sperm and can end with a single act of sexual intercourse. Any additional investment from the father during the child's formative years is beneficial but not essential for the survival of the child to reach adulthood (Goetz and Shackelford 2009; Trivers 1972).

Differential parental investment provides an important general principle underlying evolutionary hypotheses of mate choice by specifying that the greater the level of obligatory parental investment required of one sex relative to the other, the more stringent that sex should be when selecting potential mates in order to avoid costly errors associated with mating and production of offspring (Trivers 1972). Sex differences in obligatory parental investment also lead to differences in variability of reproductive success, or reproductive variance, between males and females (Brown

et al. 2009). As competition over the scarce and valuable sexual and parental resources of females results in some males being more successful than others, males often experience greater reproductive variance than females, therefore providing the evolutionary impetus for competitiveness, risk-taking, and gambling for mating success in males (Hawkes 1990) and conversely selectiveness and cautiousness in females (Buss 2006). As a result of these differences, the mating strategies of males and females diverge in order to increase the benefits and reduce the costs of mating for each sex: The high minimum obligatory parental investments required of females mean that having sex with more mates does not increase (and may even lower) their reproductive success, whereas placing a premium on the *quality* of mates is the preferred strategy. In contrast, the low minimum obligatory parental investments required of males mean that males are capable of increasing their reproductive success by focusing on obtaining greater mating *quantity* (Brown et al. 2009).

Parental investment theory elucidates two important components underlying Darwin's (1871) sexual selection theory, namely, intrasexual competition where members of one sex compete for access to the valuable higher-investing opposite sex and intersexual selection where the higher-investing sex exerts selective preferential mate choice over members of the other sex. The costs associated with fast and indiscriminate mating are therefore generally higher for females than for males. For many species, including humans, because females are the higher-investing sex, they evolved to be more careful, discriminate, and stringent during mate selection and are more likely to engage in intersexual selection by exercising greater preferential mate choice over mates compared to males. This in turn drives behaviors that facilitate greater intrasexual competition in the lower-investing males to contest other similarly eager conspecific males for sexual access to selective females (Buss 2006), greater risk-taking to exploit the odds of reproductive variance (e.g., Reaney and Backwell 2007; Wilson et al. 2010), and greater preference for sexual variety to increase the quantity of mates (e.g., Brown 1974), compared to females.

Examples of Parental Investment Theory

Sex differences in intersexual selection and intrasexual competition can be observed across a wide variety of species. For instance, elephant seal pups are nursed solely by females, while males do not invest in the care of offspring. Male elephant seals have also been observed to accidentally kill their own pups when they attempt to copulate with mates in the harem. The high value of the sexual and parental resources provided by female elephant seals drives fierce competitiveness among males, as only one third or less of the males can secure a mate during any breeding season (the highest-ranked males acquire at least half of all the matings; Le Boeuf 1974).

The greater reproductive variance of males relative to females also drives behaviors in males that maximize mating quantity through aggressiveness and risk-taking. For instance, risk-taking was found to predict aggression and mating success in male fiddler crabs, and this was independent of their body size (Reaney and Backwell 2007). Likewise, aggressiveness and exploratory behavior is correlated with mating success among European house crickets (Wilson et al. 2010).

The Coolidge effect is a phenomenon seen in mammalian species that facilitates the pursuit of sexual variety, where males (and to a lesser extent females) exhibit renewed sexual interest if introduced to new and receptive sexual partners. A study of rats found that males that were allowed to copulate to exhaustion were more sexually rearoused by novel females as compared to familiar females, indicating that reduced desire to copulate was not due to exhaustion but rather familiarity (Brown 1974). In fitness terms, fertilization becomes fairly likely after several consecutive copulations, so continued sexual activity with the same female likely faces sharply diminishing returns.

Intrasexual competition also drives the evolution of exaggerated traits and displays in the males of various species, as can be observed from the antlers of stags, tusks of elephants, and plumages of peacocks. Male satin bowerbirds do not partake in offspring care nor associate with the female after mating, but males compete by expending

significant time and energy to build large, specialized, and highly elaborate nest structures known as bowers to attract females (Borgia 1985).

Whereas male intrasexual competition tends to be more prevalent than female intrasexual competition, the evidence for female choice is more often observed than male choice in species that have greater obligatory parental investment in females than males. In the earlier example of satin bowerbirds, females exercise selectivity based on the males' bower-building prowess (Borgia 1985). During the mating season for koalas, females exercise selectivity over which males are capable of emitting the most low-pitched mating calls that signal large body mass, which is an indicator of high mate value. In insect species such as the water strider, females have evolved abdominal spines that serve to thwart the advances of sexually eager and harassing males and reduce the frequency of costly matings (Arnqvist and Rowe 1995).

Although obligatory parental investment is often greater in females than males, the males of some species contribute a larger obligatory parental investment than females. In these cases, the sex role is reversed, and the males of those species are the more selective sex, while the females intrasexually compete for the males (Trivers 1972). Among pipefish and seahorses, the females transfer their eggs onto specialized egg-brooding structures located on the males' tails during mating, where they are nourished throughout the entire duration of gestation. The females thus evolved to be brightly colored in order to compete intrasexually to be selected by the males, while the males preferentially choose the most attractive and brightly colored females as their mates (Wilson et al. 2003). In a bird species known as the *Phalaropus lobatus*, the female phalarope's obligatory parental investment only consists of laying the eggs in the nest. In contrast, the male phalarope builds the nest himself, incubates the eggs, and looks after the young alone. As predicted by parental investment theory, the females aggressively court the males and compete with each other to be selected by the males. Sex-role reversed species therefore strongly validate parental investment theory, as the theory specifies that

greater levels of minimum obligatory parental investment correspond with greater selectiveness, rather than specifying that females should always be more selective than males (Trivers 1972).

In sum, sex differences in the amount of obligatory parental investment toward offspring drive the underlying components of sexual selection. The high-investing sex (with greater mating cost) evolves to be stringent and choosy over mates, while the low-investing sex (with lower mating cost) evolves to be competitive with members of their own sex for mating opportunities, that is, access to the high-investing and thus more valuable opposite sex (Buss 2006).

Implications of Differential Parental Investment for Human Sex Differences and Mating

The general principle of differential parental investment that guides sex differences in mate choice among nonhumans provides important insights for understanding human sex differences and mating. This section highlights a few of the key sex differences between men and women as predicted by their relative obligatory parental investment.

Sexual Strategies

Asymmetries in obligatory parental investment between the sexes incentivize distinct sexual strategies differently such that mating costs are decreased and mating benefits are increased for each sex, therefore serving each sex's unique reproductive interests. For ancestral women who lived without modern food production, public health, and social welfare, being impregnated or having children without the commitment of a reliable mate carried heavy costs (Daly and Wilson 1983). Thus, in reproductive terms, the costs of noncommitted, casual sexual relationships typically outweigh the benefits for women more so than for men. Accordingly, women evolved to prefer a selective, long-term mating strategy to procure the lasting commitment of a good quality mate who can provide protection and resources, while men evolved to be more eager than women

to engage in casual, short-term sexual relationships in order to increase their quantity of mates (Buss 2006).

Risk-Taking

As men experience greater reproductive variance than women given that they can sharply increase their reproductive success by increasing mating quantity, men generally stand to benefit more than women from being open to risks and uncertain opportunities (Hawkes 1990). A study of road crossing found that males are more likely than females to put their safety at risk and cross a busy road to catch a bus, and males are also more likely to attempt risky road crossing when they perceive the presence of females in the vicinity, but females do not show a comparable effect in relation to the presence of males. Indeed, studies have found that women have generally lower appetites for risk than men, and this is partly due to men experiencing less distress than women when placed in risky situations (Campbell 1999). An experimental study of male skateboarders also found that the presence of an attractive woman elevated their testosterone levels and produced an increase in risky stunts attempted and completed (Ronay and von Hippel 2010). Sex differences in mating outcomes as indicated by differential parental investment and reproductive variance may therefore dictate that, on average, men will be paid more handsomely than women to have a higher risk appetite.

Aggression

Differential parental investment predicts that men are more likely than women to be physically aggressive in order to win at intrasexual competition and emerge dominant over intrasexual competitors (Campbell 1999). As high-investing females also carry valuable sexual and parental resources, the cost of losing these resources as a result of physical aggression is also high. While some researchers have argued that both men and women have the same capacity to aggress, female aggression consists mainly of subtle and indirect verbal behaviors, such as ostracism, as opposed to males' direct verbal and physical assaults, and when weapons are used, women use less physically harmful tools than men (Campbell 1999).

Sexual Conflict

Conflicts arise because the ways in which each sex distributes their limited reproductive resources are not always in the best interest of the other sex. As men have a stronger preference for short-term relationships and stand to benefit more from maximizing mating quantity than women, men will have a stronger desire for sexual variety and will be more sexually persistent, whereas women, who have a strong preference for committed long-term relationships, will be more sexually restricted than men (Buss 2006). This difference in preference thus predicts that men are more likely than women to sexually harass the opposite sex, while women are more likely than men to downplay, thwart, or frustrate the sexual advancements of the opposite sex. Goetz and Shackelford (2009) therefore argue that historically and cross-culturally, men are more likely than women to be the perpetrators of sexual coercion and rape, while women are more likely than men to be the targets.

Sexual Misperception and Commitment Skepticism

Men and women's differing awareness and assessments of the opposite sex's intentions also arise from differences in mating and parenting costs. Studies have found that men are more likely than women to perceive the presence of sexual interest in a woman based on minimal cues such as a smile, a touch on the arm, or mere friendliness (Haselton and Buss 2000). On the one hand, this relative overperception on the part of men is likely an adaptation to facilitate the enactment of a short-term mating strategy, given that, for men more so than for women, inferential errors leading to missed sexual opportunity carry greater reproductive costs compared to mistakenly inferring sexual interest. This male bias likely contributes to women's experience of unwanted sexual advances (Goetz and Shackelford 2009). On the other hand, just as women underreport their number of sexual partners (Smith 1992), they may be underrepresenting their sexual interest in ambiguous situations. Additionally, there may be other adaptive female biases at work. For instance, women, more than men, report falsely leading

on members of the opposite sex to believe that they are sexually interested when they are not (Haselton et al. 2005). Friendly behaviors toward men may, consciously or subconsciously, be adaptive ways for women to encourage interest from a wide number of male suitors and to extract resources and encourage demonstrations of value and commitment from such men. Furthermore, the incentive to be choosy compels women to be skeptical about a man's commitment even when it may be sincere, as the reproductive costs to women of wrongly inferring that a man is committed are immense (Haselton and Buss 2000).

Jealousy

Jealousy is an emotional state that is aroused by a perceived threat to a relationship and motivates behaviors to counter such threats (Buss et al. 1992). As fertilization and pregnancy occur in women, they are guaranteed full certainty of maternity. In contrast, men cannot be certain that the offspring is theirs (Geary 2005). As a result, men experience intense jealousy from acts that signal sexual infidelity by their female partners, as sexual infidelity from partners put men at risk of having their mating effort and resources redirected to another man's offspring, thus unknowingly assisting the reproductive success of another male at the expense of their own (Buss 2006). Indeed, the experience of jealousy from a partner's sexual infidelity has been found to be less severe for a woman than a man (Buss et al. 1992). Instead, women experience more jealousy when their mates are involved in emotional infidelity, as this translates to the man channeling his parental efforts and resources away from her and her offspring toward mating rivals and their offspring (Buss 2006).

Sexual Regret

When asked about their regrets in life, men are more likely than women to report wishing that they had slept with more partners, whereas women are more likely than men to wish they had tried harder to avoid poor choices of sexual partners (Roesse et al. 2006). Various forms of sexual regret (Galperin et al. 2013; Roesse

et al. 2006) can also be derived from the distinct errors that the sexes sought to avoid but ended up committing. Women, more than men, regret indiscriminate sexual actions, such as having a one-night sexual encounter or having sex with someone who led them to believe they were interested in a relationship but in fact turned out to be only interested in having sex (Galperin et al. 2013). Conversely, men, more than women, regret sexual inaction, such as failing to respond to a sexual invitation or missing a sexual opportunity (Roesse et al. 2006).

Evolution of Nonobligatory Male Parental Investment

The biology of internal gestation and obligatory postpartum suckling, as well as the associated sex differences in the opportunity and potential benefits of seeking multiple mating partners (Brown et al. 2009; Trivers 1972), account for the large sex differences in observed intrasexual and intersexual competition and mating behaviors in mammals. Although these factors give rise to a greater preference for casual and short-term sexual relationships in men than women, human males are unique among mammals for also having a preference for long-term relationships and investing significantly in offspring. When humans select mates for a long-term relationship, both sexes are intersexually choosy, and females also demonstrate intrasexual competitiveness for males who are willing to contribute significant (though nonobligatory) investments to offspring. The phenomenon of human paternal investment is therefore exceptional and extraordinary.

While uncommon in mammals, obligatory paternal investment is found among many bird, fish, and insect species (e.g., Thornhill 1976). In humans and other species, because paternal investment is not always required for offspring survival, it is nonobligatory and facultatively expressed; that is, it varies with proximate conditions. Nonobligatory paternal investment in a species can arise when such investments significantly improve offspring survival rates and when there is a high degree of paternity certainty (Geary 2005).

The facultative expression of male parenting in humans thus reflects trade-offs between the costs and benefits of parental investment in the ecological context of the male, and males may evolve to invest significantly in offspring if doing so increased their own fitness.

Offspring Survival

As the brain size needed for effective survival increased in the hominin lineage, childhood periods became progressively longer due to the longer duration needed by human offspring to develop their mental faculties. Children are thus altricial (i.e., helpless and dependent at birth), and long-term pair bonding and paternal care enhanced the fitness of the men engaging in it. By providing protection and nurturance to offspring, men can increase the likelihood that offspring can reach reproductive age, are capable of acquiring mates, and can produce viable offspring (Geary 2005). In many forager societies, children without an investing father have lower survival rates than those with one (e.g., Hill and Hurtado 1996). In industrial societies, one trait that is strongly associated with social competitiveness and mate value is educational achievement. Paternal investment, including income provided to the family and direct care, is correlated with better academic skills and upward social mobility in children, even when controlling for maternal investments (Amato 1998). Paternal involvement in play also helps develop the social competence of offspring. For instance, children whose fathers regularly play with them are more likely to be socially accepted and liked than children who lack such fatherly involvement (Carson et al. 1993).

A man's fitness can also be indirectly increased through parental investment regardless of increments to offspring survival. Men who demonstrate a willingness to commit and invest in children are regarded as desirable and can therefore raise their own mate value and attract mates themselves (Buss 2006). A man who shares the costs of parenting with his mate can also reduce her workload and calorific costs associated with raising offspring (Marlowe 2001), which may increase her fertility and accordingly enhance the man's fitness.

Paternity Certainty

In reproductive fitness terms, a male that invests in another conspecific rival's child suffers large costs to himself and his own legitimate offspring. As discussed earlier, men experience intense jealousy in response to their partner's actions that signal sexual infidelity, thus serving as an evolved affective defense against such reproductive costs (Buss 2006). Correspondingly, men are also more likely to invest in offspring when they have confidence in those offspring being theirs – in other words, when paternity certainty is high (Geary 2005).

For many species, cuckoldry is a gamble on the part of females that typically involves trade-offs between the risk of losing a primary mate's investment (upon his discovering that she is having sexual relations with someone else) versus the opportunity of gaining additional social and material support from extra-pair males, higher-quality genes for her children, or both (Geary 2005). In species where the investment provided by males is obligatory, these investments are virtually guaranteed, and hence there is low variance in male investments to offspring. Cuckoldry rates are thus low as females have no incentive to gamble for additional investments from other males and risk losing the investment of their primary mate. Conversely, for species where male investment is nonobligatory, cuckoldry rates vary with male quality; females paired with low-quality mates often risk the loss of their primary mate's investment and attempt to copulate with better quality mates when the opportunity arises. A similar variation in cuckoldry rates is reflected in human societies (Anderson et al. 2007). The significance of paternity certainty to male reproductive fitness is evidenced by the rise of marital arrangements and the universality of the paternity presumption in marital arrangements (i.e., the legal determination that a man is "presumed to be" a child's biological father without additional supportive evidence) across cultures, which serve to establish and enforce men's exclusive access to their mate's reproductive capacity and, ultimately, to ensure their paternity certainty.

Thus, contrary to most mammals, human males form long-term pair bonds and invest significantly in offspring insofar as paternity certainty is high and paternal investments can increase men's fitness. Paternal investment has evolved because it contributes to the reproductive fitness of offspring (and thus, to both parents) and women have evolved to look for signs of a man's ability and willingness to invest in offspring when they seek long-term mates.

Conclusion

Differential parental investment guides the evolution of preferred sexual strategies and mating behaviors of reproductively successful parents to optimize their own reproductive fitness. Across many species, including humans, females have a greater minimum obligatory parental investment than males to ensure offspring survival, which has tended to select for sexually choosy and discriminating females and sexually eager and competitive males. The different costs associated with parenting and mating for males and females have implications for intrasexual competition and intersexual selection which lead to differences in their preferred sexual strategies, aggression and risk-taking, perception of potential mates, and the mating conflicts they experience. While these sex differences in mating preferences do exist, men may also pursue a long-term mating strategy and provide nonobligatory parental investments under facultative circumstances where their fitness can be increased.

Differential Reproductive Success

Veronica Kraft¹ and W. Jake Jacobs^{1,2}

¹Department of Psychology, University of Arizona, Tucson, AZ, USA

²Department of Psychology, Wilson College, Chambersburg, PA, USA

Definition

A measure of the number of offspring (or replications) a particular individual, group, or gene left behind relative to others.

Introduction

Differential reproductive success consists of a statistical analysis of the outcome of a class of mechanisms that, according to Darwin's Theory of Evolution by Natural and Sexual Selection, produces changes in the distribution of variants within populations. According to the essence of Darwin's theory, *differential selection* acts on *variations in fitness*, which produces *differential reproductive success* over time. To clarify our

concept of differential reproductive success, we must first define both differential selection and variations in fitness.

Differential Selection and Variance of Fitness Are Devices to Achieve Greater Differential Reproductive Success

Differential selection refers to a class of selective pressures that disfavor (or favor) some members of a population over others. The mechanics of differential selection may differ with any given level of analysis.

Variation in fitness consists of two interrelated concepts: variation and fitness. *Variation* is a descriptor for differences that exist within a population. *Fitness* is a measure, the gold standard of which is set relative to a dynamic set of causal factors that favor some variants in a population over others (differential selection). Taken together, *variation in fitness* provides a measure of the success or failure (differential success) of any given variant in a population. (The term “*fitness*,” as used here, is a moving average measure of how well an individual member of a population solves extant adaptive problems leading to reproductive success relative to other members of the same population. Hence, *fitness* is a moving average that provides an estimate of an entity (and its copies) that, when compared to the competitor fitness, quantifies progress toward *differential reproductive success*.)

Working together, differential selection operates on variations in fitness in a way that produces differential reproductive success over time. *Differential Reproductive Success* involves at least three components. The first component consists of the abstract construct *reproduction* – defined as the production of one or more copies of an entity. The second component consists of the measurable construct *reproductive success* – defined as actualizing one or more copies of an entity or event. The third component, *differential reproductive success*, consists of several measurable subcomponents – (a) an individual, by whatever means, actualizing one or more copies of

itself that (b) outnumber the actualized copies of individuals in direct reproductive competition, that (c) engage in the same process during each subsequent generation.

Taken together (i.e., over generations), *differential reproductive success* documents an increase in percentage of the population occupied by successfully copied entities and their characteristics.

These measures make no reference to the survival of the strongest individual or to individuals outliving others. Instead they are measures of success, relative to competitors, in leaving copies of individual replicators in future generations. For example, how likely genes will successfully replicate relative to other genes (Barash and Wilson 1982). In this example, genes with the greatest fitness relative to the mechanisms of extant differential selection – replicate through generations of individuals (sometimes referred to as “vehicles”) via each successive generation of individual differential reproductive success. Those genes with the greatest fitness, by definition, out-reproduce the genes of less fit genes. Over generations, genes that out-reproduce less fit genes come to represent a greater proportion of a species population (Buss 2012).

Conclusion

These inherited fitness variations are byproducts of natural selection; variations in fitness leads to greater reproductive success for some than for others – which equals greater differential reproductive success relative to others in the same group. The idea of fitness resulting in differential reproductive success applies to individual entities and to higher- (e.g., groups- or species) and lower- (e.g., gene or replicator) level entities.

Differentiation

Aleksandra Pilarska
Institute of Psychology, Adam Mickiewicz
University, Poznań, Poland

Synonyms

Articulation; Complexity; Individuation

Definition

Differentiation refers to a process of change in a system toward greater complexity or the result of such a process (i.e., the complexity of a system's structure); in a somewhat narrower sense, differentiation is concerned with the number of specialized elements in a complex system.

Introduction

The concept of differentiation has long been central to several psychological theories. Witkin et al. (1962) discuss the notion of *psychological differentiation*, viewed as an organism-wide process of development toward greater psychological complexity. At the core of Bowen's (1978) family system theory and therapy is the concept of *differentiation of self*, considered as a key aspect in the process of emotional development and maturing. Child psychology and psychoanalysis use the term differentiation interchangeably with the term *individuation* to denote a process through which a child develops a self (e.g., Mahler et al. 1975). In all the above theoretical approaches, differentiation is conceived of as the developmental task. The idea bears resemblance to the use of the term in biology, where organismic differentiation is assumed to increase phylogenetically and ontogenetically. Greater differentiation is expected to be associated with increased specialization of elements and functions of a given psychological system, and carries implications ultimately for the relations with the environment –

a more differentiated system is characterized by separation between what is recognized as internal and external to the self. Implied here also – as the organizing response to increasing differentiation – is an increasing degree of integration. Indeed, this relationship between differentiation and integration may be seen as the basic law of development, best known as the orthogenetic principle. It states that “Wherever development occurs, it proceeds from a state of relative globality and lack of differentiation to states of increasing differentiation, articulation, and hierarchic integration” (Werner 1957, p. 126).

The three theoretical conceptualizations outlined above as well as other meanings of the concept of differentiation are briefly explored below.

Witkin's Psychological Differentiation

The concept of psychological differentiation has its origins in Witkin's (1949) earlier work, which focused on the stylistic tendencies that cut across perceptual and intellectual functioning. Using various perceptual tasks such as the body-adjustment test (BAT), the rod-and-frame test (RFT), the rotating-room test (RRT), and the embedded-figures test (EFT), Witkin and his coworkers demonstrated that consistent individual differences exist in the tendency to overcome embedding contexts. These individual differences account for the dimension of cognitive style called *field dependence-independence*. Studies of the field dependence-independence have led Witkin to the conclusion that these cognitive styles are linked to a variety of personal characteristics, all of which are manifestations of a broader dimension of personality functioning, namely psychological differentiation (Witkin et al. 1962).

The main indications of psychological differentiation include mode of structuring experience, extent of definition of the self-concept, articulateness of body concept, and mechanism of impulse regulation. Highly differentiated individuals maintain an analytical approach to problem solving, have a sense of separate identity, experience their bodies as having definite

boundaries, and are more likely to employ more specialized defenses (e.g., rationalization, isolation). Conversely, those low in psychological differentiation have a global cognitive style, lack clear body boundaries, rely on external sources for definition of their beliefs and of their views of themselves, and tend to use more primitive defenses (e.g., repression, denial; Witkin et al. 1962).

Small but consistent gender differences were found in the area of psychological differentiation, with men being more differentiated than women. Also, some ethnic groups, like Mexican-Americans and Eastern Europeans, are believed to have cultural backgrounds which favor lesser differentiation qualities (Witkin and Berry 1975).

Bowen's Differentiation of Self

Differentiation is defined by Bowen as an instinctually rooted force "that propels the developing child to grow to be an emotionally separate person, an individual with the ability to think, feel, and act for himself" (Kerr and Bowen 1988, p. 95). At the same time, there is a counterbalancing force – togetherness – that spurs the child and family to think, feel, and act alike. Well-differentiated families are characterized by interaction patterns that facilitate an age-appropriate balance of the two forces.

According to Bowen (1978), differentiation of self is a multidimensional construct. On an intrapsychic level, it is viewed as the ability to separate thinking and feeling. Individuals who are able to choose between being guided by their intellect or their emotions are those whom Bowen believed to have an enhanced sense of *solid-self* (also called basic, real, or differentiated self). Conversely, those prone to let their emotions override their thinking are those believed to be operating out of *pseudo-self* (also called pretend or fused self). The solid-self is made up of firmly held beliefs, convictions, and life principles, while the pseudo-self lacks beliefs and convictions of its own and reacts to others around it. On an interpersonal level, differentiation of self entails comfort with both intimacy and autonomy in relationships.

Differentiated individuals are capable of taking the I-position in relationships, meaning they are able to adhere to a clearly defined self without the need to conform to others' expectations. On the other hand, those who struggle with the differentiation process tend to remain fused in or emotionally cut-off from their relationships.

The Bowenian concept of differentiation has been operationalized with several self-report measures. However, only the Differentiation of Self Inventory (DSI; Skowron and Friedlander 1998) can be said to capture all aspects of differentiation (i.e., emotional reactivity, fusion with others, emotional cut-off, and taking the I-position).

Mahler's Self-Object Differentiation

Within the Mahlerian scheme of development, differentiation refers to the process, in which the child becomes able to "separate out and to differentiate his self-representations from the hitherto fused symbiotic self-plus-object representations" (Mahler 1967, p. 749). The process takes place from about 5–9 months and is considered to be the first subphase of an overall process known as *separation-individuation* process (the three remaining subphases being practicing, rapprochement, and constancy). According to Mahler, at the time children have completed the separation-individuation stage, they arrived at psychological birth, marked by a sense of being a separate individual entity. Clinical evidence implicates disturbances in the separation-individuation phase in the later development of adult psychopathology, particularly borderline personality disorder and schizophrenia (Mahler et al. 1975).

Characteristic features of the differentiation period include customs inspection (i.e., examining the mother's face and hair), a double sensation of touch (a single sensation in the child's fingers is produced by touching the mother's body, whereas all own-body exploration produces a double sensation), the peek-a-boo game, and craning (i.e., supporting own head and neck when carried; Pine 2004). These activities are believed to produce the experience of self-mother differentiation. An important marker for the latter is the 8-month

anxiety (also called separation or stranger anxiety), often emerging in children at this age.

Other Applications of the Concept of Differentiation

Theorists and researchers have made extensive use of the concept of differentiation. It has been invoked in several fields of research into cognition. Originating from Kelly's (1955) personal construct theory, the concept of *cognitive differentiation* (or complexity) is understood as the "relative number of different dimensions of judgment used by a person" (Tripodi and Bieri 1964, p. 122). Operationally, differentiation in an individual's construct system is usually defined as the number of nonidentical ratings of various interpersonal figures (e.g., mother, brother) along a set of bipolar construct dimensions (e.g., friendly vs. aloof). Several studies have demonstrated that individuals with greater cognitive differentiation fare better than less differentiated individuals when exposed to information-overloaded environment and when confronted with contradictory information (e.g., Press et al. 1975).

Social-cognitive research on the self-concept has used the term *self-concept differentiation* to refer to an individual's tendency to view oneself as possessing different personality characteristics across different roles or contexts (Donahue et al. 1993). Of note, the authors posit that high self-concept differentiation is indicative of a divided self and unresolved intrapsychic conflict. A related line of research has focused on yet another feature of the self-concept structure, namely, *evaluative differentiation* (also referred to as compartmentalization). It is defined as the extent to which positive and negative information is clustered within one's self-aspects, with high evaluative differentiation being associated with high, although unstable, self-esteem (Showers 1992).

Applied to the study of emotion, *differentiation of emotional experience* refers to the propensity to make subtle distinctions within emotion categories. It is termed as an aspect of emotional complexity, the other aspect of which regards the

range of one's emotional experiences. Emotional complexity is conceived as a product of cognitive complexity, personality dispositions (such as private self-consciousness and openness to experience), and life experiences, and has been shown to lead to empathic understanding of others' feelings and greater interpersonal adaptability (Kang and Shaver 2004).

In addition, the concept of differentiation has been used by social psychologists to describe the diversity of functions, roles, ranks, cultures, and interests in a society (i.e., *social differentiation*).

Conclusion

There is a plethora of psychological literature that addresses differentiation. Some authors treat differentiation as a general personality trait that extends across various areas of psychological functioning. Other researchers deal with it as a domain-specific psychological state. All these applications seem to share the notion that differentiation serves structuralization and specialization of psychological functions and systems.

Digit Ratio

John T. Manning¹ and Bernhard Fink²

¹Applied Sports, Technology, Exercise and Medicine (A-STEM), Swansea University, Swansea, UK

²Institute of Psychology, University of Göttingen, Göttingen, Germany

Synonyms

2D:4D; Estrogen; Finger length; Prenatal sex steroids; Testosterone

Definitions

Effects of prenatal sex steroids on fertility, behavior, and health.

Introduction

Digit ratio (or 2D:4D), i.e., the relative length of the 2nd digit ("index finger"; 2D) and the 4th digit ("ring finger"; 4D) has attracted the attention of scholars for many years (Baker 1888; Minami 1952; Phelps 1952). At the center of this interest lies the sex difference and ethnic variation in 2D:4D, and the appearance of the sexual dimorphism in 2D:4D at a very early stage in ontogeny.

Digit ratio is sexually dimorphic with males typically having longer 4th digits relative to 2nd digits than do females (male 2D:4D < female 2D:4D). The sex difference in 2D:4D suggests an involvement of sex steroids (primarily testosterone [T] and estrogen [E]) and a developmental origin that predates puberty and may indeed extend back to the 1st trimester of pregnancy. In 2D:4D, we may have a relatively fixed record of the influences of T and E during a narrow developmental window in early pregnancy. If this is so, we can use 2D:4D to address many questions regarding the etiology of sexually dimorphic abilities (e.g., speed, stamina, strength), behaviors (e.g., aggression, criminality, risk-taking), disorders of development (e.g., autism, attention deficit hyperactivity disorder, dyspraxia), and major diseases (e.g., heart disease, many cancers, osteoarthritis). There are differences in mean 2D:4D across large ethnic groupings (Caucasians, Blacks, East-Asians) in the fetus and adults (Minami 1952), and across smaller groupings such as the nation-states of Europe (Manning and Fink 2011a). They hint at in utero hormonal variation in humans, which may be driven by sexual selection and contribute to group differences in, e.g., marriage systems and susceptibility to sex-dependent diseases. Furthermore, the group and sex differences in 2D:4D may have a reach beyond that of *Homo sapiens* to other taxa within the primates (Nelson and Shultz 2010) and could indeed map on to other

mammalian groups including the rodents (Zheng and Cohn 2011).

Measurement of Digit Ratio

The most accurate measure of digit length is from radiographs that include the three phalanges. However, experimenters are often unable to take X-rays of the hand, and where there is a pre-existing archive of X-rays, it has often been of the left hand only. Soft-tissue measurements of digit length are more common and are usually taken from the ventral surface of the digit. There is a limitation with this approach as the proximal measurement point excludes approximately half of the proximal phalanx. Direct measurement of digit length has acceptable repeatability, but is more time-consuming than indirect measurement (e.g., from photocopies or scans). However, the latter method causes a reduction in 2D:4D, which is influenced by sex (greater in males than females). The effects of indirect digit measurement are a matter of debate (Manning et al. 2005), and there are concerns regarding the “clarity of report” regarding these effects (Ribeiro et al. 2016).

Sex differences in Digit Ratios and Their Stability

Digit ratio shows sex differences (2D:4D males < 2D:4D females) with low-to-medium effect sizes (Cohen's *d* from about 0.20 to 0.60; Manning 2002). Some of this variation is influenced by measurement protocol (greater for indirect than direct 2D:4D; Hoenekopp and Watson 2010) and by variation in the strength of sexual selection across populations (Manning et al. 2014a). However, we must also bear in mind that 2D:4D is a composite trait and that effect sizes for sex differences may vary across the phalanges (e.g., in the mouse, Zheng and Cohn 2011).

Finger lengths grow rapidly in children. If 2D:4D is to be used as a correlate of prenatal sex steroids, it is necessary to establish whether it

remains stable over periods of rapid growth. Manning et al. (1998, 2013) have measured sex differences in right and left 2D:4D (boys < girls) in a sample of 680 Caucasian children from 2 years to 18 years. There was no significant change in mean 2D:4D or in the sex difference across year-groups. Trivers et al. (2006) have reported stability of right 2D:4D with growth in Afro-Caribbean children, but less stability in left 2D:4D. McIntyre et al. (2005) found a tendency for radiographic left 2D:4D to increase with growth in Caucasian children, but sex differences in 2D:4D within year groups remained stable. The stability of 2D:4D is enhanced because it is underpinned by bone (the phalanges; e.g., Robertson et al. 2008) and its maintenance during rapid growth is a remarkable example of the homeostasis of form.

Human Comparative Differences

There are significant differences in mean 2D:4D across the major ethnic groups such that Caucasians have higher 2D:4D than Blacks or East-Asians. This pattern has been noted in fetal ratios (Minami 1952) and in adults (Manning 2002). Within ethnic groups, there is also evidence for between-nation variation in 2D:4D. For example, in the BBC internet study (Reimers 2007) with $n > 200,000$ participants, the mean 2D:4D (across sex and hand) per ethnic group was 0.978 for Chinese participants, 0.981 for Blacks, and 0.989 for Caucasians. Within the Caucasian sample, there were significant between-nation differences that map on to variation in national values for personality scores (Manning and Fink 2011a), consumption of alcohol and cigarettes (Manning and Fink 2011b), and gender inequalities (Manning et al. 2014a).

Digit Ratios and Sex Steroids

Manning et al. (1998) suggested that 2D:4D correlates negatively with prenatal testosterone (PT) and positively with prenatal estrogen (PE). In support of this model, they reported that (i) 2D:4D was sexually dimorphic

(males < females), (ii) the dimorphism was stable across age groups 2 years to 25 years and was not affected by puberty, and (iii) low 2D:4D (particularly right 2D:4D) was associated with efficient spermatogenesis. Since the publication of Manning et al. (1998), it has become apparent that the sex difference in 2D:4D is determined by the end of the 1st trimester of pregnancy (Galis et al. 2010; Malas et al. 2006; Szwed et al. 2017) and is in general stable in postnatal growth.

Fetal Testosterone and Estrogen

There is evidence that PT levels correlate negatively with postnatal 2D:4D. Thus, children with congenital adrenal hyperplasia (CAH), a trait associated with high PT, have been reported to have lower 2D:4D than controls (Brown et al. 2002; Ciumas et al. 2009; Okten et al. 2002). Another study reported no association (Buck et al. 2003), but overall a meta-analysis found significant associations between low 2D:4D and CAH (Hoenekopp and Watson 2010). In contrast to CAH, men with Klinefelter's syndrome (47, XXY; which is accompanied by low PT) have higher 2D:4D than population norms (Chang et al. 2015; Manning et al. 2013; Savic 2014). It is to be noted that insensitivity to T should remove variation in 2D:4D that is related to PT, but leave the variation that is linked to PE. Berenbaum et al. (2009) and van Hemmen et al. (2017) reported that T-insensitive individuals had increased mean 2D:4D, but variation in 2D:4D was still present. Their result is supportive of a PT:PE link with 2D:4D.

In studies that assessed hormonal concentrations in amniotic fluid, PT:PE ratio and PT were found to be negatively correlated with 2D:4D (Lutchmaya et al. 2004; Ventura et al. 2013), and T in maternal serum was reported to be positively correlated with children's 2D:4D (Barona et al. 2015; Ventura et al. 2013). With regard to perinatal cord blood, we should not expect to find correlations between 2D:4D and T and E because sex-dependent variation is established some 6 months before birth. However, associations were reported between low 2D:4D and high-functioning T-producing prenatal

Leydig cells that have their origin early in gestation (Mitsui et al. 2015).

The Ancient Origin of 2D:4D

Manning (2002, 2008) suggested that the sexual dimorphism of 2D:4D is an ancient trait, which may have its origin in the evolution of four-limbed animals. Sex differences in 2D:4D are present in birds (Nagy et al. 2016) and mammals (Nelson and Shultz 2010). In rodents, inactivation of the androgen receptor (AR) gene increases 2D:4D, whereas inactivation of the estrogen receptor (ER) gene lowers 2D:4D. The administration of exogenous PT or the blocking of ERs lowers 2D:4D, whereas administration of PE or blocking ARs increases 2D:4D (Auger et al. 2013; Talarovicová et al. 2009; Zheng and Cohn 2011). These experimental data confirm that 2D:4D is fixed by PT:PE in a narrow prenatal window and it is linked to the activation of "skeletogenic" genes by PT:PE. The genes, some 20 in number, have multiple functions, which include the morphogenesis of the skeleton, reproductive organs, and the brain (Zheng and Cohn 2011).

Digit Ratio and Sensitivity to Testosterone

A number of studies have investigated the link between low 2D:4D and high sensitivity to T. This includes studies of associations between 2D:4D and the structure of the AR and those that have reported associations between 2D:4D and administered T. Modifiers of AR function include polymorphisms in its coding sequence (e.g., variable numbers of CAG repeats), interaction with cofactors, intracellular trafficking of the T-bound complex, and interaction with general transcription factors. Over 170 proteins possess AR coactivating or corepressing characteristics, indicating that a multitude of signals converge on the AR to regulate its function (Heemers and Tindall 2007; Heinlein and Chang 2002). Some studies have reported a negative relationship between 2D:4D and CAGn, and one study found that 2D:4D in neonates was dependent on CAGn and circulating levels of T (see Hoenekopp 2013 for a meta-analysis). However, most reports have not found a correlation between CAGn and 2D:4D.

The importance of this null-finding for the putative association between 2D:4D and PT is a matter of debate. Hoenekopp (2013) has suggested that CAGn has a weak effect on AR transcription rates, and no or little or inconsistent effects on traits that are known to be strongly influenced by T. An alternative view of the correlations between 2D:4D and the AR is given by Voracek (2014). Clearly the link between 2D:4D and PT would benefit from an experimental rather than a correlational approach.

A more powerful experimental method of considering sensitivity to T is to administer the hormone and note whether 2D:4D modulates the response. It has been reported that 2D:4D modulates the effects of exogenous T application on empathy, moral judgment, cooperation, trust, preference for status goods, aggression, and brain activity associated with mental rotation task scores (Buskens et al. 2016; Montoya et al. 2013; Pintzka et al. 2016; van Honk et al. 2011, 2012 for women; Carré et al. 2015; Wu et al. 2017 for men). The direct manipulation of T itself makes this experimental procedure more powerful than correlational data. The link between 2D:4D and sensitivity to T is potentially further amplified by associations between low 2D:4D and production of T in competition-induced circumstances (Manning et al. 2014b). Thus, men with low 2D:4D, and those with lower right 2D:4D relative to left 2D:4D, tend to produce high levels of T and high T:C ratios when challenged with intense exercise and/or aggressive stimuli (Crewther et al. 2015; Kilduff et al. 2013a, 2013b).

Digit Ratios, Target Traits, and Effect Sizes

Masculinized and feminized traits are generally associated with low and high 2D:4D, respectively. Effect sizes for associations vary. The strongest correlations with 2D:4D are found for performance in sport and developmental disorders and the weakest among personality traits. Autism is a severe developmental disorder that is strongly sex-dependent such that the male-to-female sex ratio is 4 to 1 across the full IQ range, and rising to

9 to 1 in children with normal IQ. Children with autism are often unresponsive to people and lack awareness of the feelings of others (“mind-blindness”; Baron-Cohen 1995). The sex-dependent pattern of autism has led to the suggestion that it may result from the influence of high levels of PT, the “extreme male brain theory” (Baron-Cohen and Hammer 1997). Thus, it has been proposed that PT effects of hypermasculinization of the brain may cause autism.

Manning et al. (2001) considered the relationship between 2D:4D and autism in 72 children (Asperger’s Syndrome [AS]; of these, 23 participants had normal IQ), 210 unaffected relatives (88 fathers, 88 mothers, 34 siblings), and a matched normative control sample. In comparison to controls, children with autism and children with AS had lower 2D:4D, and fathers, mothers, and sibs from affected families had lower 2D:4D. These findings have been the focus of a number of replications and two meta-analyses (Hoenekopp 2012; Teatero and Netley 2013). Both studies were supportive of a correlation between low 2D:4D and autism spectrum disorder. More recently, Barona et al. (2015) reported an association between low 2D:4D and emotional and communication difficulties in a large community-based sample. However, this relationship was restricted to the lowest 10% of male 2D:4D ratios. Currently, it is unknown whether associations between low 2D:4D (high PT) and symptoms of “mind-blindness” are present throughout normative populations (as predicted by the extreme male brain theory) or whether these effects are found only among males who have been exposed to very high PT.

Digit Ratio and Sports Performance

Manning and Taylor (2001) reported a negative relationship between 2D:4D and performance across a range of sports and extended this analysis to a detailed consideration of professional soccer players. Since this initial report, there have been similar findings for other sports such as running, skiing, surfing, rugby, rowing, basketball, and Sumo wrestling, and for measures of fitness and strength. A meta-analysis confirmed the initial finding of Manning and Taylor, and found

substantial relationships but with some heterogeneity in effect sizes such that endurance sports tended to show the strongest effects (Hoenekopp and Schuster 2010).

Digit Ratio, Aggression, Risky/Criminal Behavior

The associations between 2D:4D and aggression and rule breaking show sex differences, with higher effect sizes in men compared to women (e.g., Hoenekopp and Watson 2010). There is evidence that T influences such behavior, with greater intensity of expression associated with high T (Mehta et al. 2015). It is to be expected that 2D:4D would be related to aggression, risky/criminal behavior, and dominance because 2D:4D modulates the action of T (Carré et al. 2015; Montoya et al. 2013; van Honk et al. 2011, 2012). PT is associated with neuronal loss and there is evidence of a positive relationship between 2D:4D and brain morphological features. Darnai et al. (2016) reported significant positive correlations between 2D:4D and volume measurements such as total cerebral cortex, total cerebellar white matter, and total cerebellar cortex in men but not women. Gorka et al. (2015) found low 2D:4D was associated with reduced anterior cingulate cortex gray matter volume (a brain region supporting conflict monitoring and behavioral inhibition).

Aggression

There are reliable negative relationships between 2D:4D and sports performance and many of these sports involve aggressive/competitive interactions (Hoenekopp and Schuster 2010; Manning and Taylor 2001). This pattern of significant 2D:4D effects in sports that provide intense challenge conditions is what we would expect if 2D:4D were a proxy for sensitivity to and amplitude of T-spikes. Therefore, it seems reasonable to assume that 2D:4D and aggression is negatively associated. However, the effect size of the 2D:4D and aggression relationship has proved difficult to quantify.

A meta-analysis of studies concerning 2D:4D and aggression revealed no significant relationship for women ($n = 19$ studies) and a

small but significant negative relationship for men ($n = 18$ studies, $r = -0.06$; Hoenekopp and Watson 2010). Subsequent large-sample studies have reported male effect sizes of about $r = -0.10$ (Butovskaya et al. 2013; Hoenekopp 2011).

Correlations of $r = -0.06$ to -0.10 for male 2D:4D associations with aggression are small. However, aggression is not invariant across situations but is context-dependent (Millet 2011). Thus, an interactionist perspective is necessary to understand its relationship with T. Baseline differences in T from individual to individual do not correlate strongly with between-individual variation in aggression. Rather, it is variation in spikes of T in response to challenge situations that correlate with levels of aggression (Carré and Olmstead 2015). Low 2D:4D (particularly low right-left 2D:4D) individuals tend to produce marked T-spikes on challenge with aggressive stimuli and/or intense exercise (Crewther et al. 2015; Kilduff et al. 2013a, 2013b). They are also sensitive to high concentrations of T (Carré et al. 2015; Montoya et al. 2013; Pintzka et al. 2016; van Honk et al. 2011, 2012) and show negative correlations between 2D:4D and aggression in challenge conditions (Kilduff et al. 2013b; Millet and Dewitte 2007).

Therefore, it may be that the 2D:4D and aggression correlation is significant in men when in challenge conditions, and weak in contexts other than challenges (Kilduff et al. 2013b; Manning et al. 2014b; Millet and Dewitte 2007). Support for this suggestion comes from real-world studies. Thus, in professional soccer players, there is a negative correlation between the number of yellow and/or red cards per match and 2D:4D in junior and elite players (Mailhos et al. 2016; Perciavalle et al. 2013). Similarly, patients with “boxer’s” fractures (of fourth or fifth metacarpals) acquired during street-fighting have lower 2D:4D ratios than controls (Joyce et al. 2013).

Risky/Criminal Behavior

The relationships between 2D:4D and risky/criminal behavior appear to show higher effect sizes than those found for the relationship of 2D:4D and

aggression. For example, Hoskin and Ellis (2015) reported a mean correlation of about $r = -0.40$ between 2D:4D and criminality. Hanoch et al. (2012) found a correlation of $r = -0.24$ between 2D:4D and impulsivity among offenders and non-offenders. Schwerdtfeger et al. (2010) reported a correlation of $r = -0.36$ between 2D:4D and traffic violations. Furthermore, large internet samples of 2D:4D enable us to consider risk avoidance across nations rather than individuals. In the BBC internet study, Manning and Fink (2011a) reported significant correlations for mean male 2D:4D per nation and national values of uncertainty avoidance (23 nations: right hand $r = 0.58$, left hand $r = 0.59$).

Personality

It is generally thought that 2D:4D is only weakly associated with aspects of personality such as the “Big-Five” constructs (Austin et al. 2002; Fink et al. 2004; Lippa 2006). This view may be correct. However, the field would benefit from a consideration of the context in which personality is examined. For example, in conditions such as aggressive challenge, the relationships between 2D:4D and traits such as neuroticism may change (Manning and Fink 2018).

Sexual Orientation

Interest in the relationships between 2D:4D and sexual orientation came shortly after the publication of Manning et al. (1998). Unfortunately, the first papers (Robinson and Manning 2000; Williams et al. 2000) used indirect methods (photocopies) to measure finger lengths. This practice has continued such that most studies show this limitation. A meta-analysis concluded that lesbians showed lower mean 2D:4D than heterosexual women, but the 2D:4D of gay men did not differ from that of heterosexual men (Grimbos et al. 2010). This is a surprising result which should be treated with caution. Homosexuality in men is thought to be primarily determined by early genetic and hormonal influences while homosexuality in women may be more influenced by later-life effects. Finger lengths in almost all the studies considered by Grimbos et al. (2010) were measured indirectly. The BBC

internet study concluded that lesbians and heterosexual women did not differ in their 2D:4D but gay men had significantly higher 2D:4D than heterosexual men (Manning et al. 2007). Further work on 2D:4D and sexual orientation would benefit from the use of direct digit measurement.

Digit Ratios and Health

There are possible applications for 2D:4D and diagnosis, prognosis, and response to therapeutic interventions in a number of diseases and developmental disorders.

Sperm Production

Manning et al. (1998) reported negative relationships between 2D:4D and spermatogenesis. However, this was in a sample from a fertility clinic and the participants included a proportion of men who were producing few or no sperm. The links between 2D:4D and spermatogenesis in the normative population are more controversial and need to be clarified (see Auger and Eustache 2010 for data and discussion).

Heart Disease

There is accumulating evidence that low 2D:4D in men is associated with protection against early myocardial infarction and coronary heart disease (e.g., Manning and Bundred 2001; Wu et al. 2013; Zhenghao et al. 2012). However, the correlation between 2D:4D and heart disease in women requires clarification.

Cancers

There is now much interest in links between 2D:4D and cancers that are dependent on sex steroids. We feel this is particularly important as there is the possibility that 2D:4D may be useful in prediction of susceptibility and also disease progression where the inhibition of sex steroids may be part of the treatment (e.g., Li et al. 2017). We include here cancer of the breast (Muller et al. 2011) and prostate (Rahman et al. 2010). There are now 19 papers concerning 2D:4D and susceptibility to various sex-dependent cancers (Bunevicius 2018). In order to focus attention on

Digit Ratio, Table 1 The relationships between national means of 2D:4D and age-standardized DALY's by 100,000 in 29 countries and 16 malignant neoplasms. For cancer of the breast, cervix, uterus, and ovary, the mean of female right and left 2D:4D was used, and for cancer of the prostate, the mean of male right and left 2D:4D was used

Malignant neoplasm	r	r^2	p	Adjusted p
Mouth	0.35	0.12	0.06	
Esophagus	−0.19	0.04	0.31	
Stomach	0.57	0.32	0.001	0.02 (2-Tailed)
Colon/rectum	0.05	0.003	0.79	
Liver	0.56	0.31	0.002	0.03 (2-Tailed)
Pancreas	0.23	0.06	0.22	
Lung	0.51	0.26	0.005	0.03 (2-Tailed)
Melanoma	−0.41	0.17	0.03	
Breast	−0.50	0.25	0.005	
Cervix	0.48	0.23	0.008	0.04 (1-Tailed)
Uterus	−0.11	0.01	0.57	
Ovary	0.08	0.007	0.67	
Prostate	−0.53	0.28	0.003	0.02 (1-Tailed)
Bladder	0.47	0.22	0.01	
Lymphoma	−0.07	0.004	0.73	
Leukemias	0.58	0.33	0.001	0.02 (2-Tailed)

those cancers that may be linked to 2D:4D, we present associations between overall mean 2D:4D per nation and DALY's (disability adjusted life years; [Global Health Estimates 2015](#)) of a number of cancers, including those for the stomach, liver, lung, cervix, prostate, and various forms of leukemia (Table 1).

Osteoarthritis

The relationship between low 2D:4D and risk for osteoarthritis of the knees seems to be firmly established (e.g., Ferraro et al. [2010](#)). This correlation appears to be independent of wear-and-tear consequent on engagement in sport or other physical activity (Haugen et al. [2011](#)). Further work is indicated regarding 2D:4D and prognosis and response to treatments.

Smoking and Alcohol Choices

Smoking and the consumption of alcohol are major public health issues. In the BBC internet study, Manning and Fink ([2011b](#)) reported correlations with 2D:4D such that low 2D:4D was linked to high alcohol intake and smoking to high 2D:4D. These correlations applied to individuals and to mean 2D:4D per country and

national levels of consumption of cigarettes and alcohol. Further work is necessary to identify the relationships between 2D:4D, health (heart disease, lung cancer, respiratory conditions), and consumption of tobacco and alcohol).

Conclusion

In humans, 2D:4D is a sexually dimorphic trait (male 2D:4D < female 2D:4D) that is more or less fixed by the end of the 1st trimester of pregnancy, and which is little affected by puberty. It is a composite trait such that the sexual dimorphism may differ between the phalanges. The sex difference in 2D:4D is ancient among the four-limbed vertebrates with similar sex-dependent ratios in mammals (rodents and primates). There is experimental and correlational evidence for the influence of prenatal sex steroids on mammalian 2D:4D. Low 2D:4D is associated with high PT low PE and high 2D:4D is related to low PT and high PE. Digit ratio is determined in a narrow fetal time-window and the effect sizes of correlations with target traits depending on whether such traits are influenced in that time-window.

There are large effect sizes in the relationships between 2D:4D and sport (particularly sports that are dependent on endurance) and developmental disorders. Effect sizes are smaller with regard to complex sex-dependent behavioral traits that are difficult to measure. A potentially important aspect of 2D:4D are its links with sex-dependent diseases such as cancers, heart disease, and osteoarthritis.

Our understanding of 2D:4D has advanced considerably since the late 1990s. However, the speed of this advance has been affected by the many methods that have been used to measure finger length. The lack of clarity of report concerning this issue means that we still do not understand the properties of various indirect methods of digit measurement. This apart, we feel that the diverse program of research into 2D:4D will continue to reveal the importance of the prenatal hormonal environment on behavior, physiology, and predisposition to disease.

[Imitation of sounds](#); [Onomatopoeia](#); [Origin of language](#)

Definition

The ding-dong theory constitutes an early theory of the origins of spoken language postulating that the meaning of the words derives from what things sounded like.

Introduction

The idea behind the early speculative theory of ding-dong theory is sound symbolism which is a nonarbitrary connection between phonetic features of linguistic items and their meanings. Max Muller at the early stages of his work on the evolution of language proposed the ding-dong theory by stating that meaning comes from sounds. According to this hypothesis, the origin of language emerged evolutionary with the names our ancestors gave to objects, activities, and natural occurrences after an identifiable sound associated with it in real life (Mandavilli 2016). An important characteristic of this notion is the fact that words having high front vowels were used to name small or jagged objects in comparison to words having round vowel which were used to name large or round-shaped objects. It is suggested that people used sound symbolism to give meaning to words through onomatopoeia, which is the formation of a word by the imitation of a sound made by or associated with its referent in real space and time. “Boom,” for example, was the word given for explosion (Mitchell et al. 2013).

A major drawback of this theory is that onomatopoeic words are not the same in every country because the sound and pronunciation of the words are not similar among the different languages. People in different nations used their onomatopoeic words which are formed in regard to how they interpret different sounds. These words are a very limited part of their vocabulary since many ideas such as love, hate, harmony, and the sea do not make any noise. For this reason, this theory was later abandoned by Max Muller (1877).

Conclusion

According to the ding-dong theory, a connection was established between language and the

quality of the things which were part of our ancestors. It refers to the concept that there was a relation between the sounds made and the comprehension of the surroundings. The origin of language, therefore, emerged by the connection between the meanings of words and the sounds that were made by the early human beings.

The limitation of this theory is that it does not explain the origination of different ideas or things that do not produce any sound. This results to a limited vocabulary of the languages. Thus, there cannot be an explanation of the origin of names of such concepts, if this theory is chosen as the origin of language. Besides, the relationship between meaning and sound is not established by any convincing evidence.

Definition

Using sexual intercourse as a form of mate guarding, keeping partner from straying, and reducing risk of extra pair copulation.

Introduction

Mate guarding refers to strategies that seek to preserve access to mate, hinder reproductive rivals in gaining access to partner, derogate rivals and competitors, and keep the partner from defecting the relationship (Buss 2002). While there are various forms of mate guarding tactics utilized within relationships (see, e.g., Arnocky et al. 2014; Buss and Shackelford 1997), here frequency of intercourse as a mate guarding strategy within couples is presented.

Frequency of in-pair copulation and mate guarding behaviors have been found to be positively associated (Shackelford et al. 2006), both self-reported by men in relationships and from women reporting on mate guarding behavior from partner. This suggests that men's mate guarding behavior and in-pair copulation function concurrently as anti-cuckoldry tactics, and other studies have found such association to be moderated by mate value of partner (e.g., attractiveness in Kaighobadi and Shackelford 2008) and own mate value (e.g., height in Brewer and Riley 2009). Women who reported more frequent in-pair intercourse also performed other retention tactics (such as enhancing appearance) at a higher frequency (Barbaro et al. 2015). While couples seem, to some extent, to have the same perception of what kinds of tactics are being used to mate guard within a relationship (Shackelford et al. 2005), and mate guarding behavior and intercourse frequency is linked, motivation for sexual intercourse in itself is also related to mate guarding.

Both sexes use intercourse to increase partners' sexual satisfaction, hence increasing relationship commitment (Barbaro et al. 2015), reducing the chance of mate defection. Engaging in intercourse has also been found to be a means of keeping partner away from potential rivals or consolidate a relationship. At least two studies investigating reasons for having intercourse found that women and men use sex in order to keep partners in relationships, to keep partner happy, to reduce the likelihood for partners to cheat by having sex with her/him and having sex with someone due to fear of him/her having an affair if sex was not had, and to "trap" partner into a new relationship (Meston and Buss 2007; Kennair et al. 2015). These are all reasons that are linked to mate guarding and potentially function to reduce possibility of mate poaching and relationship defection. While there are few sex differences in the reasons for engaging in sex related to reduction in mate poaching, there are suggestions of sex differences in ultimate explanations for frequency of in-pair copulation.

Multiple studies have shown that men increase sexual interest toward partner, increase distress and persistence in response to partners sexual

rejections, and even increase forced in-pair copulation, as a function of time spent away from current partner (e.g., Shackelford et al. 2007; Starratt et al. 2007; Goetz and Shackelford 2006). This has been suggested to be behaviors that evolved in response to increased chance of infidelity and sperm competition (for a review of sperm competition in humans, see Shackelford and Goetz 2007). Women seem to a larger degree to engage in in-pair copulation in order to increase partner's commitment to the relationship in order to reduce partner investment in rivals (e.g., Barbaro et al. 2015).

Conclusion

Sexual satisfaction is associated with relationship satisfaction (e.g., Byers 2005; McNulty et al. 2016), and by definition in-pair frequency of intercourse is identical between women and men in relationships. However, there are suggested sex differences in how frequency of intercourse is used as a mate guarding tactic, with sperm competition and eliciting relationship investment differing between men and women.

Definition

The ability of humans to discriminate between odorous stimuli perceived either from the right or from the left side.

Introduction

Our sensory systems have developed in order to allow us to identify stimuli in the environment, evaluate them, and make sensible decisions about them (Kringelbach and Stein 2010). Olfaction is of great importance for food selection and reproduction (Porter et al. 2007). Olfactory sensory neurons can detect a large variety of odors and process the information by sending them through their axons to the olfactory bulb. The human perception of an odor is usually associated with pleasant or unpleasant emotions (Mori et al. 1999). The question that has been researched widely in the past decades is whether humans are able to define the direction of an odor, in other words, the ability to discriminate between odorous stimuli perceived either from the right or left side.

Kobal et al. (1989) define directional smell as:

the ability to localize an odor source in space by perceiving the differences of the odor's concentration reaching both nostrils, with a higher odor concentration on the nostril closer to the odor source stimuli with accuracy.

Is There Directional Smell?

Since a sound source can be localized because emitted pressure waves reach each ear at a slightly different phase, one might also assume that a source of smell could also be localized by differences in time or intensity with which the different odors reach the nostrils (Kobal et al. 1989). Von Békésy's research experiment (1964) indicated that if the time difference and the difference in sensation intensity of an olfactory stimulus is used, the direction of an olfactory source can be determined between the two nostrils as the air surrounding the odorous object is inhaled.

Therefore, according to Von Békésy (1964), the direction of a smell can be determined with precision in spite of the small distance between the nostrils and human sense of smell process, an equivalent to the phenomenon of directional hearing. More recent research (Van Toller et al. 1980; Prah and Benigus 1984; Hummel et al. 2003; Wysocki et al. 2003; Frasnelli and Hummel 2005; Villarreal et al. 2012) supports odor localization mediated by the olfactory nerves and a strong consensus that humans can localize olfactory/trigonal exists.

Various research experiments have been conducted to date, in order determine the existence of directional smell. Contradictory to von Békésy's findings, Skramik stated that substances that merely stimulate the olfactory nerve cannot be localized, but if the substances additionally excite the trigeminal nerve, then it is possible to distinguish between right and left side (Von Skramlik 1925 in: Kobal et al. 1989). The trigeminal nerve is connected with the sense of pain, cooling, warming, or pressure; hence, if the odors elicited such effects, distinction between right and left was possible. In their experiments, Schneider and Schmidt (1967) obtained similar results when they used coffee, *n*-butane and ammonia presented to both sides of the nose in two different concentrations and again with two different arrival times. Because in their experiment less than half the participants were able to localize either the strong odors or the odors presented first, they added head rotation to the sniffing procedure and all three odors were accurately localized as to left, right, and center. They concluded that directional smell requires additional information from the trigeminal and/or the position sense.

In the last decade, research seems to be supporting the existence of olfactory localization. Despite the evidence that localization of an odor is possible only if the odor stimulates the trigeminal nerve, some evidence that active sniffing may affect this ability and facilitate the localization of pure odorants exists. Frasnelli et al. (2008) tested the ability of participants to localize a pure odorant and a mixed olfactory/trigeminal stimulus under two stimulation conditions, active or passive. The results indicated that subjects could only localize the mixed olfactory/trigeminal stimulus, but there was significant interaction between

stimulation condition and nature of the odorant. What was interesting in their findings was that participants had more correct answers after stimulation of the right nostril than of the left nostril, which may suggest laterality effects (Zatorre and Jones-Gotman 1990; Frasnelli et al. 2010). Although the activation of olfactory receptors is essential to the smell process, most odorants simultaneously stimulate the trigeminal system (Doty et al. 1978). Kleemann et al. (2009) investigated the human sensitivity and ability to localize hydrogen sulfide, which in low concentrations stimulates the olfactory system, and trigeminal substances including carbon dioxide. Their results demonstrated that humans are not able to localize substances which only activate the olfactory system independent of their concentration despite of their aware perception, but they possess an ability to localize odorants that additionally excite trigeminal system. Moessnang et al. (2011) investigated olfactory localization using implicit spatial cueing which suggested the existence of spatial information processing in the olfactory system. They concluded that humans are unable to explicitly localize the odorant under immobile conditions with passive stimulation, but they suggested that odor localization has implicit effects on behavior, thus supporting directional smelling in humans (Moessnang et al. 2011).

Additionally, a number of studies argue that human phylogenetic heritage has not entirely disappeared. Porter et al. (2005) contrasted olfactory left versus right localization with olfactory identification during brain imaging, by delivering odorants to the left or right of the nose. They found nostril-specific neural activity in primary olfactory cortex that was predictive of behavioral localization accuracy. The same region has been implicated in auditory and visual localization as well (Calvert et al. 2001). According to Moessnang et al. (2011), these findings imply increased sensitivity of implicit tests for spatial abilities in human olfaction, which may help to reconcile the conflicting results concerning directional smelling in previous studies. Research points to evidence that the nature of an odor influences the ability of humans to localize it (Brand and Jacquot 2001; Brand et al. 2001). Porter et al. (2005) found that regions that are classically

understood to be visual processing centers are also activated during olfactory identification. From their findings, they concluded that humans can spatially localize an odorant to the left or right, when behavioral conditions are optimized (Porter et al. 2005).

Conclusion

Research to date has shown that when pure odorants are used as stimulants localization is random (Kobal et al. 1989). On the other hand, stimulation of the trigeminal somatosensory system simultaneously can lead to directional orientation. Research (Kobal et al. 1989) shows that directional smelling exclusively mediated by the olfactory nerve does not exist. Olfactory localization can be allocentric, egocentric, trigeminal, or pure olfactory. According to Porter et al. (2005), in any occasion it must be subserved by neural substrates that research is yet to explore. Future research should aim to establish the existence of directional smelling through the investigation of patients with olfactory or trigeminal deficits.

Disabilities

Katherine Brophy
University of South Carolina – Beaufort,
Bluffton, SC, USA

Synonym

[Impairment](#)

Definition

Conditions that inhibit the learning educational material and/or social interaction with peers in the classroom.

Introduction

In 1975, Congress passed the *Individuals with Disabilities Education Act* (IDEA). Originally called the *Education for All Handicapped Children Act*, IDEA mandates the provision of a free and appropriate public school education for eligible students ages 3–21. The primary goals from IDEA is to protect the rights of children with disabilities, and to give parents a voice in their child's education. Children that have a disability that need special education and related services also receive a Free and Appropriate Public Education (FAPE). FAPE believes that students with

disabilities are entitled to an education that is appropriate for them, and must be provided to every eligible school-age child with a disability. All students with disabilities who are eligible for FAPE will be educated at the public expense, and FAPE will also be implemented in the public-school system that the student is in. Public-schools are required to provide special education in the least restrictive environment which means that they must teach the students with disabilities in general education classrooms whenever it is possible. Under the *Individuals with Disabilities Education Act* (IDEA), this law gives parents specific rights and protections, which is called procedural safeguards, to make the educational decisions for their child. IDEA covers Autism, deaf-blindness, deafness, emotional disturbance, hearing impairment, intellectual disability, multiple disabilities, orthopedic impairment, other health impairments (including ADHD), specific learning disabilities (including dyslexia, dyscalculia, and dysgraphia), speech or language impairment, traumatic brain injury, and visual impairment (including blindness) (Lee 2014).

From 2014 to 2015, people who are receiving special education services from the ages 3 to 21 years-old were 6.6 million, or about 13% of students with special needs as public-school students (National Center for Education Statistics 2017). Among those students receiving special education services from public-school, 35% had specific learning disabilities (National Center for Education Statistics 2017). Even though a student has a disability, it does not guarantee the child getting special education services unless the result of that disability needs special education services to make progress in school. For instance, a student with ADHD can be doing well in school and would not be covered by the IDEA. A child who is not eligible for support under the IDEA can still be eligible for support under the *Section 504 of Rehabilitation Act*. The *Section 504 of Rehabilitation Act* is a federal law that requires a school district to provide a free and appropriate public education to each child with a disability in the district and this federal law can provide accommodations to help children in school (Lee 2014).

Evaluating Disabilities

To be able to get a child the help he or she needs, first the child must go through the evaluation process called a Comprehensive Educational Evaluation. The evaluation process will be conducted by either a psychologist or a special education teacher where they will either evaluate or observe the child. Then a case manager, or sometimes called an IEP coordinator, will coordinate all the testing to see if the child needs an Individualized Education Program (IEP). An IEP is a plan that details the support and services at the school that will provide to meet the individual (the child) needs of a student with a disability who qualifies for special education. The parents, one of the child's general education teachers, at least one special education teacher, school district representative, a school psychologist or other specialist, and the child (when the child is 16 years-old) will be at the IEP meeting to talk the Present Level of Performance (PLOP), annual goals, and individualized supports and services. PLOP is a statement about a child's current levels of academic and functional performance, which includes social, behavioral and motor skills, and goals. The IEP will need to be revised as the child makes progress and faces new challenges each year, and then the new instruction techniques and technology become available (Morin 2014).

Learning and Social Disabilities

Individuals with Disabilities Education Act (IDEA) covers learning and social disabilities, and some disabilities can flow through both learning and social disabilities (Lee 2014). Disabilities that are learning include Auditory Processing Disorder (APD), Dyscalculia, Dysgraphia, Dyslexia, Language Processing Disorder, Non-Verbal Learning Disabilities, Visual Perceptual/Visual Motor Deficit, and related disorder include, Attention Deficit Hyperactivity Disorder (ADHD), Dyspraxia, Executive Functioning, and Memory. IDEA also uses the term Specific Learning Disability (SLD) which is a disorder in one or more of

the basic psychological processes involved in understanding or in using language, spoken or written, which disorder may manifest itself in the imperfect ability to listen, think, speak, read, write, spell, or do mathematical calculations. SLD includes a range of disabilities including, but not limited to, dyslexia, aphasia, issues with perception, and brain damage (American Speech-Language-Hearing Association 2017). Some children who have learning disabilities can be less observant in their social environments, misinterpret the social behavior of others at times, and may not learn as easily from experiences of social cues as their classmates. While other children who have learning disabilities, they can exhibit an immaturity and social ineptness due to their learning disability. Learning disabilities arise from neurological differences in the brain structure, function, and can affect a person's ability to receive, store, process, retrieve or communicate information. Learning disabilities are still undergoing considerable progress to map some of the characteristics but people believe that it could be a consequence of developing brain before or during birth, involving such factors as significant maternal illness or injury, drug or alcohol use during pregnancy, maternal malnutrition, low birth weight, oxygen deprivation and premature or prolonged labor. Early recognition for children that may be at risk with a learning disability can prevent years of struggle and self-doubt.

Social disabilities include Autism Spectrum Disorder (ASD), Specific Language Impairment (SLI), Learning Disabilities (LD), Language Learning Disabilities (LLD), Intellectual Disabilities (ID), Developmental Disabilities (DD), Attention Deficit Hyperactivity Disorder (ADHD), and Traumatic Brain Injury (TBI). Social communication disorder can include problems with social interaction, social cognition, and pragmatics that can be either a distinct diagnosis or occur within the context of other conditions. Social communication behaviors that include eye contact, facial expressions, and body language, are influenced by the sociocultural and individual factors of the person (Learning Disabilities Association of American 2017).

Laws Protecting Disabled People

The *Americans with Disabilities Act* (ADA) is another civil rights law that protects people with disabilities from discrimination in schools, work-place, and other environments. ADA protects people who have a physical or mental impairment that substantially restricts one or more major life activities, this also includes learning. This law prohibits employers from using unnecessary qualification standards to weed out applicants with disabilities, but no requiring employers to hire unqualified applicants with disabilities. Employers are also prohibited from referring to inaccurate job descriptions to determine that an employee with a disability can no longer perform his or her job, and failing to provide reasonable accommodations that do not cause undue hardship to them (Cortiella and Horowitz 2014).

The *Elementary and Secondary Education Act* (ESEA) is another federal law focusing specifically on disability that includes students with disabilities. The ESEA was first passed in 1965 as part of the President Lyndon B. Johnson's war on poverty, and in 2001, is known now as the *No Child Left Behind Act* (NCLB). The ESEA requires schools to meet standards for educational content and student achievement, schools to measure student achievement and progress annually in reading and math, and schools must provide data on overall student performance as well as on programs made by discrete student group, including students with disabilities (Cortiella and Horowitz 2014).

The National Assessment of Educational Progress (NAEP) is the only nationally administered measure of student academic achievement in reading math that is given to students in fourth and eighth grade. The NAEP has three levels, Basic, Proficient and Advanced, that measure what students should know and are able to do at each grade assessed. The NAEP also reports the proportion of students whose scores place them below the Basic achievement level. It shows a wide and persistent achievement gaps between students with and without disabilities in both reading and math but there has been no significant improvement seen in

NAEP for students with disabilities from 2009, 2011, to 2013 administrations (Cortiella and Horowitz 2014).

Risk Factors for Children with Learning and Social Disabilities

Children with disabilities are faced with many challenges that include protective and risk factors. Some common risk factors in a child's developmental path with disabilities include temperament, developmental delay, early antisocial behavior, disturbed peer relationships, and biological/genetic factors. There are environmental risk factors for delay and psychopathology, which include chronic poverty, lack of parenting skills, parental psychopathology, chronic family discord, and lack of social support for the child and the family members. There are also risk factors that have been identified in relation to school failure, school dropout, and substance abuse (Morrison and Cosden 1997).

"Researchers have also identified protective factors, or variables associated with resiliency, for a variety of outcomes" (Morrison and Cosden 1997, p. 45). No one factor has been directly associated with the development of later problems, even though there are many risks and proactive factors that have been identified (Morrison and Cosden 1997). Protective factors can ameliorate problems that are often associated with learning disabilities that can also reside in the person's other skills or temperament or in the responsiveness of the environment to the individual and the ecocultural fir of the individual to the environment. The presence of learning disabilities is a risk factor because of the wide variations in the emotional and social adaptation with people that have learning disabilities (Morrison and Cosden 1997).

Risk factors can be internal, like the function of a specific neurological characteristics that can affect behavior, or it can be external, like the structure of family, peers, and societal environments which can result in frustration. On the other hand, protective factors can ameliorate problems that are often associated with learning disabilities,

which can reside in the individual's other skills, temperament, responsiveness of the environment to the person, and the ecocultural fit of the person in the environment. The ecocultural fit acknowledges learning disabilities by the affected person, with his or her family, and other people in the environment. So, a person can see their disability as all-encompassing or discrete in ecocultural fit. Social expectations and values can put a person with learning disabilities at risk for failure at school and in other social environments, or can help protect that person (Morrison and Cosden 1997).

People with learning disabilities tend to score higher on the scales of anxiety and depression than do other people who do not have known disabilities. People with learning disabilities that have anxiety and depression are found to have self-esteem and self-awareness. They can have higher levels of self-awareness and self-esteem which is correlated with lower levels of anxiety thus self-awareness and self-esteem is a protective factor. Many people with learning disabilities do not have significant emotional problems but there is a correlation with people who have learning disabilities appear to have a greater risk for depression and anxiety. Family environment can be a different story because having a child with a learning disability may add to the family stress in several ways. Parents will have different types of interactions with their children because of problems of information processing at home and school with their children who have learning disabilities. Parents are required to interact more with the school personnel where their child attends which can add more stress on the family (Morrison and Cosden 1997).

Children that have hyperactivity have also been noted as a risk factor for the family functioning because it can be associated with less support and less control for the family with a child that has a learning disability. A parent's goal with having a child that has a learning disability is understanding the nature of the child's disability, and not generalizing the child's disability to the whole child. Protective factors in families with a child who has a learning disability, are more effective in

responding to their child's needs, both cohesive and flexible, demonstrate affective support for the child, and utilize coping skills to use at home and with their interactions at the school (Morrison and Cosden 1997).

Academic performance of students with learning disabilities is compromised by their high rate of disciplinary removals. One in two students with learning disabilities experiences a suspension, in or out of school, or expulsion, but students with emotional disturbance receive more disciplinary removals (Morrison and Cosden 1997). Disciplinary removals will continue to be problematic for students with learning disabilities until school implement evidence-based practices proven to reduce problem behavior. Dropping out of school is a major societal problem with both the impact on the person who drops out and as a general indicator of educational and economic decline. People with learning disabilities have a significantly higher rate of school drop than students without disabilities. The drop-out rate for students with learning disabilities has dropped to 19% in 2011 versus 35% in 2002, but the drop-out rate varies widely across states (Cortiella and Horowitz 2014). People with learning disabilities who have also dropped out of school are at risk for extended economic and social disadvantage. Risk factors that include students with disabilities that drop out are prior school attendance, discipline problems, reading ability, socioeconomic status, family intactness, school transfers, and suspensions and/or expulsions. Any type of school practices that lead to student alienation, disengagement, and loss of commitment to children with learning disabilities also contribute to the dropout problem. Adjustment problems, an experience of school failure, peer problems and/or family disruptions are associated with subtypes of people with learning disabilities that dropout of school. Some people with learning disabilities can successfully negotiate their work environments, make friends, and gain alternative educational credentials outside of the school environment after dropping out of school. Within the special education programs, having small class sizes with low student-teacher ratios, responsive

educational programs, individual attention, basic skill instruction, and parental involvement have helped with the successful dropout prevention for children with learning disabilities. Increasing the graduation rate and reducing the drop-out rate continues to a high priority for parents and educators, especially with the importance of a regular high school diploma, and detrimental and lifelong effects of dropping out of school.

Transitioning from post-school life is a required part of every student's Individualized Education Program (IEP) from the IDEA. According to Cortiella and Horowitz (2014), 54% of students with learning disabilities had the goal to attend a 2 or 4-year college, 43% would like to attend a vocational training program, 57% wanted to obtain competitive employment, and 50% wanted to live independently in 2013 (p. 22). Parental expectations are important, as they are associated with levels of student achievement and general post-high school outcomes (Cortiella and Horowitz 2014).

Conclusion

Disabled children are exposed to the same societal challenges as other children but the existence of a learning disability can put the disabled person at a greater risk for negative emotional, familial, and societal outcomes. Risk factors for people with learning disabilities can have internal factors that make the person more vulnerable to negative outcomes which include certain types of nonverbal learning disabilities, impulsivity, hyperactivity, and denial of a person's disability. Schools can provide the supportive environment and skills necessary for positive coping strategies for children with learning disabilities, but higher levels of school disruptions, unsuccessful school performances, and family separations often lead to school dropout for people with learning disabilities. Many interventions have focused on the remediation of academic problems associated with people who have a learning disability. When a child is diagnosed with a learning disability, they are set into

motion for a set of academic and school structure modifications to help the child with their academic needs. However, understanding the impact of these factors for children with learning disabilities will help enable other people to reduce many of the secondary problems associated with having a learning disability.

Delayed discounting; Temporal discounting

Definition

The decrease of perceived value of a particular item as time passes.

Introduction

All types of organisms are constantly making choices throughout their lives. Some of these choices are simple, with one alternative clearly better than the other. However, other choices that must be made are less clear-cut. When human beings and other organisms make decisions, how do they actually analyze and decide between two alternatives? When faced with the choice between two items that differ only on one factor, individuals should pick a larger value over a smaller value, a reward available sooner over a reward available later, and a more certain reward over a less certain reward (Green and Myerson 2004). These are the basics that determine how organisms make the best possible choices. Nevertheless, this only explains one simple type of choice; in reality, most choices are much more complex and differ on many factors. When multiple conditions are examined together, individuals must make tradeoffs to make their decisions.

Perceived Value Changes as a Function of Time

When organisms must make decisions with multiple conditions to consider, the determining factor is the value that they assign to individual components of a choice. The changes in this value for various reasons allow organisms to select one choice over another when neither are wholly better than the other. The perceived value of an item declines as a function of temporal distance, or time, from the present moment. This is called the discounting of future returns. To illustrate: \$100 now is the same monetary value as \$100 in 30 days; the amount has not changed. However, according to temporal discounting, an individual will perceive the \$100 as less valuable 30 days in the future. This helps to explain how organisms make decisions when multiple factors are involved. Various changes to the two options in delay discounting tasks can result in different choices – and different perceived values assigned to the objects – on the part of participants. For instance, making the later reward a larger absolute value or reducing the delay for receiving the larger reward will both result in a higher perceived value for the later reward when all other factors are kept the same. This change is often referred to as choice reversal and is the interest of study in many research areas. One way to look at how organisms discount future returns is by mathematically describing it.

Economists often use an exponential discounting function to explain how the subjective value of an option decreases by a constant percentage per time unit. The equation is as follows:

$$V = Ae^{-bD} \quad (1)$$

In Eq. 1, V is the perceived value of a future return, A is the amount of the return, D is the delay of receiving the return, and b is a parameter that is the rate of discounting. Equation 1 is often criticized because by itself it cannot predict the choice reversal. However, Green and Myerson (1993) have stated that this model can predict the reversal

if the discounting rate for a larger amount is assumed to be lower than the discounting rate for a smaller amount.

There is another popular equation used to study discounting. This equation is referred to as a hyperbolic function. In delayed discounting, a hyperbolic function is often used to model how the values of two choices differ as temporal distance increases (Mazur 1987).

$$\frac{V = A}{(1 + kD)} \quad (2)$$

In this equation, V is equal to the present value of the reward, A is the value of the reward, D is equal to the time of the delay of the reward, and k is the discounted parameter rate of decrease in value (Mazur 1987). This equation can often lead to one of the lines depicted in Fig. 1.

As time increases, the present value of the two rewards will change according to a hyperbolic function. In Fig. 1, there are two different hyperbolic functions. The solid line represents the smaller reward, and the dotted line represents the larger reward. At point B is the reception of a smaller, sooner reward, and at point C is the reception of a larger, later reward. At point A, the two lines intersect, and the smaller reward becomes more valuable than the larger reward. This reversal of the options is because the time has increased, and the second option is now preferable after a significant amount of delay.

This reversal is often the focus of many studies to see at what specific point participants will

prefer each individual reward and at what point that preference shifts. Research on the discounting of future rewards is applicable to many areas of psychology because individuals discount the future more or less steeply depending on certain characteristics. For instance, some research has examined discounting rates in loan borrowers and nonborrowers, finding that loan borrowers discount the future more steeply than nonborrowers (Mahoney and Lawyer 2016). The application of the discounting of future returns has also been studied as it relates to shopping, such as for CDs in an online marketplace (Hantula and Bryant 2005). All of these areas of research are easily linked to the explanation of how organisms discount the future. However, one link that may not be readily apparent is the relationship between the discounting of future returns and evolutionary psychology.

The Discounting of Future Returns and Evolutionary Psychology

Evolutionarily, organisms also have to make tradeoffs when making decisions. For example, reproductive decisions in ancestral time can be examined for evidence of temporal discounting. Over time, organisms have had to make many decisions regarding immediate versus delayed rewards, and these decisions have varied across different ecologies. To return to the previous example, an organism in an unstable environment may discount future returns more steeply and may choose to have offspring sooner because the value of future offspring decreases due to the higher chances of death before future reproduction can take place. During the life of an organism, there are many decisions that can be deemed as having a benefit in the distant future or the immediate future. The benefits of a decision for an immediate or delayed reward are specific to whether that choice would be advantageous in the current environment. In addition, some individual differences exist in individuals' decisions to receive items sooner rather than later, and, therefore, in the amount that individuals discount future returns. An organism will have an overall preference for

Discounting of Future Returns, Fig. 1 Two rewards discounted as a form of delay

now or later, and this preference can be beneficial or harmful depending on the environment of the individual. These preferences are theorized about in life history theory, which differentiates these preferences as a fast strategy (immediate rewards) and slow strategy (future rewards). Life history theory has been used to explain many different aspects of behavior, but more importantly for this chapter, it has been used to explain how specific tradeoffs are made in many aspects of behavior (e.g., time versus money) (Griskevicius et al. 2010). This theory also helps explain individual differences in the discounting of future returns.

The Discounting of Future Returns and Life History Theory

An individual's life history strategy has been shown to influence how that organism discounts future returns. Life history theory says that all individuals must make tradeoffs when deciding how to allocate resources to maximize fitness, but environmental factors, particularly in infancy, influence how organisms make these decisions throughout their lives (Ellis et al. 2009). Life history strategies vary both between and within species; humans have a slow life history relative to many other species, but humans can also have relatively slower and faster life history strategies based on their own personal environmental characteristics and experiences. The harshness and unpredictability of the environment an individual experiences when they are young predicts whether an individual will select a fast or slow life history strategy, and this strategy influences how they make decisions about the present versus the future. Some factors related to life history theory have been found to reliably influence future discounting across populations, including sex and age.

An individual's sex and age have been shown to influence how he or she discounts future returns. For example, children and adolescents value the present and discount the future much more steeply than older adults (Daly and Wilson 2005). They are less likely to wait for a reward in

the future, choosing instead to receive gratification immediately. Additionally, males have been shown to discount future returns at higher rates than females (Kirby and Marakovic 1996). Life history theory suggests that this happens because males' life history strategy is faster and higher-risk; in other words, males have achieved reproductive fitness by using short-term strategies more than females across evolutionary history, so they have evolved to use short-term strategies in other areas as well, discounting the future more steeply than females in favor of more immediate rewards. Further, life expectancy for males is lower than for females, and this also influences their life history strategy and their discounting of future returns, because they need to select a choice that will benefit them while they are likely to be alive to receive those benefits (Daly and Wilson 2005).

Life history theory says that slower life history strategies should be associated with a preference for less risk and a higher value for the future, while faster life history strategies should be associated with more risk and a lower value for the future (Griskevicius et al. 2011b). This is because organisms with faster life history strategies expect to have a shorter life span, and the payoff for the future reward may not be realized. If an organism is unlikely to live to collect a reward, investing in the future is not a fitness-maximizing decision. Therefore, organisms with fast life history strategies should prefer more immediate rewards over future rewards, while organisms with slow life history strategies can safely invest in the future. This influence is not only present in monetary decisions; life history theory can be applicable to many different areas of life in which an organism is required to make decisions about present rewards versus future rewards.

Various empirical studies have tested the relationship between life history and future discounting across many types of decisions. For example, individuals with a slower life history strategy have been shown to prefer low risk and future-oriented financial options and express less positive attitudes toward early reproduction (including a desire to postpone reproduction to obtain more education or work experience), while individuals with a faster life history strategy

prefer high risk and present-oriented financial decisions and show more positive attitudes toward early reproduction as a response to mortality cues (Griskevicius et al. 2013; Griskevicius et al. 2011a; Griskevicius et al. 2011b).

Conclusion

Organisms take many variables into consideration when making choices, including whether it is fitness-maximizing to receive a smaller, immediate reward or a larger, future reward based on their specific situation and environmental characteristics. Life history theory can help explain some variations in the ways that individuals discount future returns; this theory can be applied to many different areas of life in which decisions must be made, from monetary choices to reproductive timing decisions to educational options. Researchers will always be interested in the various factors that influence how organisms make various decisions in the real world and in the laboratory, and this specific research can apply to decisions that organisms have made across assorted times in both the past and present.

Definition

Behavioral disease-avoidance processes help animals maintain safe distances from sources of

contagious disease, thereby reducing the need for physiological immune responses.

Introduction

Threats to survival have been a major driving force in evolution, shaping a wide range of specialized defensive adaptations. Some of the threats come in the form of the many hazards in the physical environment. Other, perhaps more potent threats come in the form of exploitation by other organisms. Predators are an obvious example, as are other members of the species competing for limited resources. Although less conspicuous than typical predators, tiny organisms that infiltrate larger organisms and cause somatic damage have posed a recurrent and pernicious threat. These tiny organisms include microbes such as viruses, bacteria, and protozoa, as well as relatively larger organisms such as hookworms. What unifies them is that they have evolved to spend at least a part of their lives within a host organism in order to complete their life cycle. When they cause disease in their hosts, they are known as *pathogens*. The effects of pathogens are wide ranging. Highly potent pathogens can seriously debilitate or kill their hosts within days, whereas less harmful ones may linger around for years, gradually undermining the host organism's ability to survive and reproduce (in the latter case, they are more commonly referred to as *parasites*).

When species face a recurrent threat across generations, evolutionary theory predicts the emergence of adaptations designed to thwart the threat or minimize the damage. So, what adaptations did host organisms evolve to deal with pathogens and parasites? From plants to animals, most organisms have evolved various internal defenses whose function is to detect and eliminate harmful microbes, and attenuate their harmful effects. In addition, animals – organisms with the ability to move spontaneously – appear to have evolved behavioral defenses against pathogens as well. These behavioral defenses involve specialized perceptual systems (vision, olfaction, gustation) and psychological processes (emotions, beliefs,

attributions), which ultimately increase the likelihood that the animals will stay away from sources of pathogens (Murray and Schaller 2016). In humans, these defenses have implications that go beyond maintaining health. Several lines of research have examined the ways in which disease-avoidance processes may influence various aspects of social life, shedding new light on topics such as physical attractiveness, intergroup prejudice, and cultural variation.

Why Did Behavioral Defense Evolve?

When it comes to natural defenses against infectious diseases, we humans are most familiar with the vertebrate immune system, which is our primary defense against pathogens. This system comprises multiple layers of physiological defenses involving specialized cells and bodily fluids, and specific responses such as fever and inflammation. Perhaps the most impressive component is the adaptive immune system (“adaptive” in the sense of adapting to different pathogens within a lifetime), involving tailored reactions to different kinds of pathogens in the body (Clark 2008). Not only does the adaptive immune system efficiently rid the body of the multitudes of pathogens that gain entry on a daily basis, it can also form a “memory” so that future invasions by the same pathogen are dealt with even more swiftly (this capacity is what makes vaccination possible). This incredibly complex and efficient immune system – which scientists have yet to fully understand – serves as a compelling example of the creative power of natural selection operating over expanses of time.

As useful and impressive as these physiological defenses are, they have a number of shortcomings. First, they are mostly reactive, doing their work only after pathogens have breached the body (although recent evidence suggests that mere perception may activate physiological defenses prior to actual contact – see below). Second, they are physiologically costly, consuming large amounts of metabolic resources, and sometimes entailing sickness behaviors which may come into conflict with other adaptive behaviors such as foraging

and mating. Third, they are not perfect, sometimes succumbing to infection (when a new, exotic pathogen enters) and sometimes overreacting to non-pathogenic agents (such as pollen, in the case of seasonal allergies). Finally, pathogens themselves evolve over time to better overcome the hosts’ immune defenses – and with much shorter generations, pathogens can evolve at a quicker pace (which can, at times, be deadly for the host species). For these reasons, in addition to behaviors for managing sickness following infection, behaviors that function to prevent pathogens from entering the body in the first place would have been highly adaptive for animals (Hart 2011). And it appears that this selection pressure shaped the evolution of animal behavior: Growing evidence indicates that animals possess behavioral defenses against pathogens. In the human literature, the suite of psychological and behavioral processes involved in disease avoidance has come to be known as the *behavioral immune system* (Schaller and Park 2011).

The behavioral immune system has two key characteristics in common with the physiological immune system: It tends to be overinclusive (responding to nonthreats more often than failing to respond to threats), and it is functionally flexible (responding more vigorously when the threat is registered to be more imminent). These characteristics will be further explicated below and will feature throughout the discussion of various aspects of disease avoidance.

Perception and Cognition

The first step in avoiding dangers is their detection, thus introducing the first key engineering problem in the evolution of danger-avoidance adaptations. For most animals, detecting bigger predators such as lions and snakes is relatively straightforward – you can usually see them, sometimes hear and smell them. In fact, it is likely that the sights and sounds of bigger predators are specifically what prey animals have evolved to respond to. But microscopic pathogens (which are essentially very small predators) elude our senses for the most part. In fact, people were

unaware of their existence until the seventeenth century, when microscopes opened up the world of microbes and helped scientists to eventually develop the *germ theory of disease*, which is the idea that some diseases are caused by microorganisms. Obviously, neither direct observation of pathogens nor an understanding of germs was necessary for the evolution of the behavioral immune system. This is because pathogens often leave behind a trail of aftereffects that can be used as cues for their detection – for example, they may change the sight and smell of food, or cause infected people and animals to exhibit overt symptoms. Also, harmful amounts of pathogens tend to be reliably found in certain objects (e.g., feces), and certain animals are especially likely to be vectors of pathogens (e.g., cockroaches). Adaptive disease avoidance can be accomplished by making use of those cues that tend to reliably co-occur with pathogens.

The cue-based nature of disease detection helps make sense of the underlying perceptual and cognitive processes. There are many examples of things that people generally do not want to touch, due to an intuitive sense that some sort of contamination may occur – moldy fruit, maggots, mucus, feces. Symptoms of disease that may usefully serve as perceptual cues include physical and behavioral anomalies such as skin lesions, fetid smells, and abnormal gait. Animals (including humans) appear to have evolved to be sensitive to these disease-connoting cues (Schaller and Park 2011). In humans, there is evidence for efficient cognitive processing of disease-connoting cues involving enhanced attention and recall, and when faced with seemingly conflicting information, people seem to be swayed more strongly by visually conspicuous abnormalities than by rational knowledge regarding the presence or absence of disease (Murray and Schaller 2016). The face may be a particularly important interface through which underlying disease is detected, as many contagious diseases alter features of the face, and observers seem to show especially strong aversion to facial abnormalities (Oaten et al. 2011). In short, ancestral humans and animals that responded with specific aversion to observable correlates of pathogens were more

likely to survive and reproduce, thus propagating those tendencies. We are descended from a long line of humans (and prehuman ancestors) who never died from contagious disease before reproducing at least once.

Relying on cues to detect pathogens is useful and has served animals well, but it does need to overcome a crucial problem, with important ensuing implications: Not all pathogens produce detectable cues (e.g., some pathogens do not produce any symptoms, especially in the earlier incubation period), and things that appear very similar to disease-related symptoms (such as burn scars) may in fact be harmless. This means that inferences based on cues will inevitably be imperfect, sometimes under-inferring disease (failing to detect actual pathogens) and sometimes over-inferring disease (“detecting” pathogens where they do not exist). In the absence of perfectly reliable cues, it is impossible to eliminate errors, but the system can be calibrated toward making one type of error, in order to reduce the likelihood of the other type of error (much like household smoke detectors that are deliberately calibrated to be hypersensitive, leading to many annoying false alarms, but, presumably, very few misses – no alarm when there is a fire – which can be highly costly). Many evolutionary psychologists have argued that under-inferring disease is much more costly than over-inferring disease in terms of survival and reproduction, and so perceptual systems should have evolved to be biased toward errors of over-inference, which will minimize errors of under-inference (Haselton and Nettle 2006; Kurzban and Leary 2001). As a result, much like smoke detectors prone to false alarms, humans will quite often “detect” diseases where none exists – that is, show a tendency to be over-inclusive in cue-based inferences regarding disease. Furthermore, because the tendency to be over-inclusive will have greater payoffs when the probability of actual infection is higher, this tendency is expected to be functionally flexible, being heightened in response to perceived vulnerability to disease – which has been empirically documented (Miller and Maner 2012). The over-inclusive nature and the functional flexibility of disease detection have interesting implications not

only for social perception and cognition but also for emotions and motivations.

Emotion and Motivation

We do not usually question our intuitions regarding things that are alluring or repugnant – it is simply obvious to us, for instance, that babies are cute and feces are revolting. Even Charles Darwin (1872) could not fully shake off this intuition-driven circularity when he defined disgust as a reaction to “something revolting, primarily in relation to the sense of taste, as actually perceived or vividly imagined” (p. 250). It is thus a somewhat underappreciated insight that the adaptive logic of disease detection and avoidance explains *why* unsightly symptoms and fetid smells are subjectively experienced as unsightly and fetid – ancestral animals and humans who found these stimuli aversive (and thus were motivated to avoid contact with sources of pathogens) would have outcompeted those who found the stimuli appealing (and had no motivation to avoid sources of pathogens). Of course, some learning does take place with regard to associating specific locally available cues with aversion (with the result that there is some cross-cultural variation in what things are considered repulsive and need to be avoided), but the basic negative response itself is unlikely to be a product of learning. There is increasing evidence that disease avoidance constitutes a distinct motivational system (Murray and Schaller 2016) and that the key emotional experience associated with disease avoidance is *disgust* (Curtis 2013; Oaten et al. 2009).

What kinds of things are disgusting? In recent decades, several groups of researchers have compiled massive amounts of data to address this question. Although it appears that human disgust has evolved to serve multiple functions (Tybur et al. 2013), a commonality running through most of the things that reliably elicit disgust across cultures and time periods – rotting food, skin lesions, maggots, bodily fluids, dirty hands – is the potential for transmission of parasites and pathogens (Curtis 2013). In other words, disgust may be an innate emotion that is reliably activated

in the presence of sources of pathogens. Or, as Pinker (1997) put it, “disgust is intuitive microbiology” (p. 383). And this intuition seems well attuned to the nature of microorganisms. Unlike toxins with safe dosage levels below which they may be harmless, many pathogens have no safe dose, because they can proliferate very quickly. This may explain why people have the sense that “anything that touches a yucky substance is itself forever yucky” (Pinker 1997, p. 383). As a result of this (perceived) association, people will find their favorite foods inedible after it has come into contact with something that is typically associated with disgust (such as a fly swatter, even if it is brand new and obviously clean). This sort of response appears to be further exaggerated in people with anxiety disorders centered on contamination fears. (By contrast, certain toxins like caffeine and alcohol are, despite their bitter taste, avidly consumed by many people.)

Interestingly, disgust may act as a psychological complement to the physiological immune system, being dialed up in response to the physiological system being compromised – for instance, due to recent infection or pregnancy. In other words, when our bodies are more susceptible to pathogenic infection, the behavioral immune system may compensate by heightening our disgust response, making it more likely that we will stay away from potential sources of pathogens. This process appears to be mediated by specific hormones, indicating that the behavioral and physiological systems are closely intertwined. Furthermore, studies have shown that disgust (or the mere perception of disease cues) can directly prime the physiological immune system, seemingly preparing the body for potential infection (reviewed in Murray and Schaller (2016)). The close relationship between the physiological and behavioral components of disease avoidance is further discussed below.

Before leaving the topic of emotions and motivations associated with disease avoidance, it is also important to mention *nausea*, which is a more specific physiological response related to disgust. Nausea is the sensation of uneasiness associated with the urge to vomit, and this response may function to quickly rid the body of

harmful substances (which includes, but is not limited to, pathogenic substances). Thus, nausea tends to occur in situations in which something has been ingested, whereas disgust has a much wider array of triggers.

Behavior

What specific behaviors evolved as part of the behavioral immune system? Some pathogens are transmitted via waste products or vector organisms. Therefore, management of such pathogens would be facilitated by some sort of hygiene behavior (e.g., keeping fecal waste out of nesting sites), which has been documented in humans and nonhuman animals (Curtis 2013). Many other pathogens are transmitted via contact with the body or bodily secretions of infected individuals. Thus, minimizing the probability of infection by other individuals requires physical avoidance, particularly avoidance of direct contact. Indeed, there are many examples of such avoidance behavior in nonhuman animals (e.g., Kavaliers et al. 2005). Chimpanzees, the closest living relatives of humans, have been found to exhibit disease-avoidance behavior: Jane Goodall (1986) observed chimpanzees maintaining physical distance from other chimps who walked abnormally as a result of polio.

In humans, most of the research has focused on the internal psychological processes (thoughts, feelings) presumed to underlie disease-avoidance behavior, partly because such research is easier to conduct and also because people are able to verbally report how they might behave in hypothetical scenarios, with at least some degree of accuracy. Nevertheless, examination of overt behavior is crucial, and there have been a few studies looking directly at disease-avoidance behaviors in humans. One study focused on an aspect of behavior that lies mostly beyond conscious control: Participants' reaction times were measured as they engaged in arm flexion (i.e., approach) or arm extension (i.e., avoidant) movements in response to visual stimuli. Consistent with expectations, participants who had been experimentally primed with information

regarding germs and diseases showed relatively quickened extension movements (Mortensen et al. 2010). In another study, participants were given a task of handling various props that they believed had just been handled by other participants, some of whom exhibited flu symptoms or a facial birthmark (as seen via video recordings). The task required participants to make different kinds of contact with the props which became progressively intimate (involving the hands, head, face, then mouth), and the researchers measured the number of participants willing to complete the task at each stage. Participants were also video recorded so that their nonverbal reactions could be assessed. The results showed that participants were far less willing to handle the props and showed stronger facial expressions of disgust when they believed that the props had previously been handled by someone exhibiting flu symptoms or a facial birthmark (Ryan et al. 2012).

This is not to say that people only avoid individuals exhibiting conspicuous markers. Today, we have a better understanding of diseases and the mechanisms of disease transmission, with the result that people also show tendencies to avoid known disease carriers (such as people with HIV) who may not exhibit any overt symptoms – although this understanding may be highly susceptible to extraneous information and bias.

Implications for Social Behavior

Animal species vary in the extent to which they are social, with solitary animals at one end (e.g., tigers) and eusocial animals at the other (e.g., ants). Sociality does not come for free, and it appears to have evolved within species when the benefits sufficiently outweighed the costs. Humans, like many other species, have evolved to be a highly social species, reaping the myriad survival and reproductive benefits of group living (e.g., greater protection against predators, mutual gains via cooperation, ease of mating). Group living generally requires physical proximity, and some interactions (e.g., mating, parenting) require highly intimate contact, all of which leave individuals more vulnerable to pathogen

transmission. Therefore, the benefits of being close to other individuals and engaging in intimate contact must be balanced against the costs of possible pathogen transmission (among other costs of group living, such as possible exploitation by other members). Clearly, the benefits have been substantial enough to put humans on an evolutionary path toward sociality – apart from rare exceptions, humans do not live solitarily, despite the fact that solitary living would be the best defense against pathogens that are transmitted interpersonally. Of course, not all individuals in our surroundings pose equally high levels of pathogen threat, and some situations are more conducive to pathogen transmission than others. Accordingly, it appears that psychological defenses against disease have evolved the capacity for discriminate and flexible sociality, allowing people to reap the benefits of group living and intimate relationships while simultaneously minimizing the potential costs.

Antisocial Implications

One obvious implication of possessing disease-avoidance processes that respond to disease cues is that, rather than harboring a blanket wariness regarding interpersonal contact, humans may have evolved to selectively avoid and exclude individuals who are more likely to be infected – which may be based on explicit knowledge and/or disease-connoting cues. As noted above, avoidance of infected others appears to have deep evolutionary roots, and Kurzban and Leary (2001) argued that this evolved tendency is likely to be one of the bases for stigmatization in human societies – that is, when people systematically avoid others who are (or appear to be) diseased, the targets experience what we refer to as stigmatization. While contagious disease is not the only reason people stigmatize others (criminals, for instance, are also highly stigmatized), there appears to be a long history of humans ostracizing other individuals with highly visible diseases and keeping them isolated (Oaten et al. 2011). Leper colonies and other instances of disease-related quarantine are examples of such exclusion.

Stigmatization involves consensual (widely agreed upon) exclusion, and so it is a more

permanent phenomenon than temporarily staying away from someone who has a fleeting infection or an illness. Indeed, disease-based stigmatization is usually reserved for those individuals who bear stable morphological markers (e.g., lepers with skin lesions) or harbor diseases believed to be permanent (e.g., AIDS). As noted above, the behavioral immune system is expected to be over-inclusive in classifying anomalous features as disease symptoms. Based on this reasoning, it has been predicted that a number of common visually conspicuous features – physical disability, obesity, facial disfigurement, birthmarks, facial features associated with old age – may be perceived as disease cues, even if people are fully aware that those features are benign. Many studies, using a wide range of methods, have found support for this conjecture. For instance, people appear to implicitly think of those physical features as being sources of contagion, and negative responses to individuals bearing those features tend to be heightened when people feel more vulnerable to disease. These findings have provided deeper insights into the psychological bases of stigmatization of morphological abnormalities (Murray and Schaller 2016).

Similar processes may underlie some instances of prejudice against members of ethnic outgroups (i.e., people of other nationalities, cultures, races). In addition to visible physical differences, ethnic outgroup members may engage in behaviors that seem “wrong” with regard to hygiene and food preparation (as different cultures have developed their own unique norms in these domains), which may trigger concerns about disease transmission. A number of research findings imply that concerns about contagious disease may underlie prejudice against ethnic outgroups (e.g., Faulkner et al. 2004). Of course, because there may be multiple reasons for excluding others, for many common prejudices, disease concerns may sit alongside other concerns and amplify negative attitudes and motivations for behavioral avoidance.

Disease-avoidance processes can contribute to antisocial tendencies even without the presence of any obvious disease cues. Sexual contact, for instance, can potentially transmit contagious

diseases, many of which may not give rise to any overt symptoms among carriers. Therefore, it can be predicted that motivations to avoid disease may be associated with reduced inclinations for sexual contact. Indeed, individuals with chronically heightened concerns about disease tend to report less promiscuous sexual behavior. Similarly, temporarily heightened concerns about disease inspire more cautious sexual behavior (Murray and Schaller 2016). More general personality traits may serve as defensive tendencies against pathogen transmission. For instance, greater neuroticism and introversion (two of the “Big Five” personality dimensions) are associated with higher anxiety about threats and reduced sociability, respectively, and so it is not surprising that chronic concerns about pathogens are associated with neuroticism and introversion (Duncan et al. 2009). There is also evidence that such personality tendencies can be temporarily primed by the apparent salience of disease (Mortensen et al. 2010).

People frequently form negative attitudes toward others on the basis of physical unattractiveness. Although not necessarily a cue for pathogenic disease, physical unattractiveness may be perceived to be associated with ill health. This can be due to an overgeneralization effect, the result of an overinclusive system that responds to any deviations from the population average (i.e., lack of a “healthy” appearance). Also, because physical attractiveness may actually serve as a signal for health in terms of resistance to pathogens and parasites (i.e., good genes, developmental stability), it makes sense that the absence of attractiveness may be perceived as a cue for the presence or the potential for disease. One way to test this would be to examine whether individual differences in pathogen disgust sensitivity (but not pathogen-irrelevant disgust sensitivity) are correlated with perceptions of attractiveness in relatively unattractiveness faces. Indeed, one set of studies found that higher pathogen disgust sensitivity was associated with perceiving relatively unattractive faces as especially unattractive; moreover, the relationship was found to be specific to disgust regarding pathogen-connoting situations (Park et al. 2012).

Prosocial Implications

Sociality is not just about physical proximity or congregating in large numbers – it is about the formation of lasting relationships. Indeed, there are many evolutionary reasons to expect animals to form strong and stable bonds. The bond between parents and offspring, for example, can be predicted from evolutionary theory: Parents who incurred costs to promote the well-being of their offspring would have been more likely to have surviving (grand)children, who would inherit those same parental tendencies (the same evolutionary process explains other forms of nepotistic altruism). One implication relevant to the present topic is that such strong bonds may dampen aversive feelings associated with disease avoidance – indeed, it has been found that mothers find their own baby’s feces less disgusting than those of other babies (Case et al. 2006).

Also, the effect of disease concerns on negative sentiments toward ethnic outgroups described above may be coupled with increased positive sentiments toward ingroup members. This may be due to the objectively lower risks posed by ingroup members (as people are more likely to be immune to local diseases); also, ingroup members may become more salient sources of support in the event of being debilitated by disease (Navarrete and Fessler 2006). Thus, although discriminatory, disease-avoidance processes can promote positive attitudes toward other people. Disease concerns may also influence views regarding the ingroup by increasing the emphasis people place on moral values pertaining to the welfare of the group (as opposed to the welfare of individuals), for example, loyalty to the ingroup and obedience to authority (Park and Isherwood 2011). Furthermore, heightened concerns about disease may translate into greater social conservatism, which also tends to be associated with exaggerated positive sentiments regarding the ingroup (Terrizzi et al. 2013). Of course, as noted above, these “prosocial” responses toward the ingroup are often coupled with antisocial responses toward outgroups, as well as toward individuals perceived to deviate from the ingroup mainstream (such as homosexuals).

Disease avoidance is associated with another type of interpersonal affection – perceptions of physical attractiveness. As already discussed above, physical attractiveness may serve as a signal for health in terms of resistance to pathogens and parasites. One contributor to facial attractiveness is bilateral symmetry, so it can be predicted that preference for symmetrical faces (over subtly less symmetrical faces) may be especially strong when concerns about pathogens are heightened. Also, such an effect would not be expected for nonsocial objects, and studies have shown evidence for this. Symmetry (as a signal for health) is important not only with regard to immediate disease avoidance, but also because it indicates the potential to produce similarly healthy offspring. For this reason, the preference for symmetry may be particularly strong in mating contexts (e.g., in heterosexual judgments of opposite-sex faces, but not same-sex faces), and there is evidence for that as well. Facial masculinity in men may be a signal for immunocompetence, and it has been found that pathogen disgust in women is associated with preference for masculinity in male faces – in other words, women especially sensitive to the threat of disease show a stronger preference for male faces displaying features associated with disease resistance (for a review of the findings described in this paragraph, see Murray and Schaller (2016)).

Culture and Cultural Differences

The operation of disease-avoidance processes discussed above may shed light on certain aspects of cross-cultural differences. The principle of functional flexibility, which helps account for the variable deployment of disease-avoidance responses (i.e., stronger responses when the threat of disease is greater), may also operate at the level of geographical regions and associated cultural groupings. To understand this, one key premise to note is that regions vary substantially in pathogen prevalence – the level of threat posed by infectious diseases. Another key premise is that many cultural norms and practices – prejudicial attitudes toward individuals who deviate from

“healthy” standards, more discriminatory attitudes regarding ingroup–outgroup relations, norms regarding eating and hygiene, and, indeed, the importance of conforming to norms – may be functional adaptations (emerging through biological and cultural evolution) that guard against disease transmission (Murray and Schaller 2016).

Putting those two premises together may explain not only why certain cultural norms exist in the first place, but also why their strengths and expressions vary across different cultures. Social scientists have noted for decades that cultures vary in the extent to which they have norms promoting individual autonomy versus group cohesion, a dimension commonly referred to as *individualism–collectivism*. Notably, higher collectivism is associated with greater social pressure against deviating from group norms and stronger ingroup–outgroup boundaries, both of which may ultimately protect against pathogens. Interestingly, research has shown that regions with greater pathogen prevalence have more collectivistic cultures (Murray and Schaller 2016). Similarly, people living in regions with higher pathogen prevalence tend to more strongly endorse moral values that promote the welfare of the group (Van Leeuwen et al. 2012). More broadly, cultures vary in how “loose” or “tight” they are, in terms of the existence of norms regulating behavior and the importance of adhering to those norms. It has been hypothesized – and empirically documented – that cultures that have historically faced higher levels of threat (including pathogens) tend to be “tighter” (Gelfand et al. 2011). Similar logic can be applied to cultural variation in personality traits (Murray and Schaller 2016).

Also, to the extent that physical attractiveness serves as an indicator for health (signal for immunocompetence, cue for lack of early-life illness), it can be predicted that physical attractiveness in prospective mates may be more strongly prioritized in regions characterized by greater pathogen prevalence. This cross-cultural variation has been documented (Gangestad and Buss 1993).

Although these findings are interesting, it must be noted that studies linking pathogen prevalence to cultural variation face important theoretical and methodological challenges, as voiced by a number of researchers (e.g., Pollet et al. 2014).

Conclusion

In this review, a distinction has been maintained between physiological and behavioral defenses, reflecting the recent evolutionary psychological research on the processes underlying disease avoidance and their implications. Clearly, the treatment of the behavioral immune system as a distinct phenomenon has been theoretically useful and empirically fruitful, generating research on previously undocumented cognitive processes, emotions, and behaviors, particularly with regard to many topics in social psychology. Of course, no psychological or behavioral process can exist in a physiological vacuum, and future research on defenses against disease will require greater integration of physiology and psychology in order to move forward. Indeed, for quite some time, many researchers have been interested in the effects of social and psychological factors on the functioning of the physiological immune system, in a field known as *psychoneuroimmunology*. Given the demonstrable ways in which the behavioral system interacts with and complements the physiological system, it has been argued that the research on the behavioral processes identified by psychologists should actually be situated within psychoneuroimmunology (Clark and Fessler 2014) and that researchers ought to think of the physiological and behavioral defenses as constituting a single integrated immune system (Gangestad and Grebe 2014). These views set the agenda for future research: It seems likely that a more sophisticated (and more accurate) picture of defenses against disease will emerge in the upcoming decades.

Disease Avoidance Hypothesis

Joshua M Ackerman

University of Michigan, Ann Arbor, MI, USA

Synonyms

Behavioral immune system; Disgust; Infection; Pathogens

Definition

The disease avoidance hypothesis refers to the set of psychological processes that promote detection of, and aversion to, temporary or chronic pathogen threats as a means of reducing infection risk.

Introduction

Pathogens and parasites have long represented critical threats to human survival and wellbeing. In fact, management of infectious disease is one of the most fundamental problems humans have confronted over their evolutionary history (Ackerman et al. 2012). Even in modern times, pathogenic agents infect hundreds of millions of people, causing approximately 9,500,000 deaths (over 16 % of all deaths) worldwide per year (World Health Organization 2008). In turn, natural selection has shaped sophisticated defenses against invading pathogens such as the complex biological mechanisms comprising the physiological immune system. Although this system is remarkably effective at managing disease threats, it is metabolically costly and imperfect in that it requires initial infection and it must continually adapt to the co-evolution of germs themselves. To address these problems, humans have evolved additional safeguards that help mitigate the probability of initial infection. The psychological collection of these defenses is termed the *behavioral immune system* (BIS; Murray and Schaller 2016).

Behavioral Immune System

The behavioral immune system consists of a suite of psychological mechanisms which functions both to improve detection of potential pathogenic threats and to defend against infection from these threats (Schaller and Park 2011). Concern about such threats directs the mind to seek out specific types of cues and, upon detecting these, to react appropriately by avoiding, expelling, or otherwise managing the danger of infection. For instance, many illnesses produce external symptoms such as sores and lesions, and accordingly, perceivers' reactions to these features are often strongly negative (e.g., Kurzban and Leary 2001; Park et al. 2003).

Behavioral immune responses can be triggered from exposure to at least three distinct sources of information. The first of these involves aspects of the environment that have been historically or ecologically linked to heightened infection risk. Regions around the world vary in terms of their pathogen prevalence, with hotter, wetter climates facilitating breeding and transmission of germs better than colder, drier climates (Murray et al. 2011; Schaller and Murray 2008). Societies that inhabit ecologies with greater pathogen prevalence exhibit differences in psychological detection and defense mechanisms compared to societies inhabiting less pathogen-rich ecologies. Second, situational cues can prompt behavioral immune activity, much as salient cues in the immediate environment influence a wide variety of social psychological outcomes. Pathogen-relevant cues include informational media (e.g., news reporting, advertising) as well as signs that other people may be infected (e.g., sneezing, coughing, bodily sores, face masks). Finally, intrapersonal elements may lead people to exert more or less effort on the detection of and defense from disease. These may involve chronic individual differences such as perceived vulnerability to disease (Duncan et al. 2009) and disgust sensitivity (Tybur et al. 2009) or temporary state changes arising from felt emotions and recent illness (e.g., fighting off infection can reduce the effectiveness of physiological immune activity, leading to

compensatory behavioral immune activity; Miller and Maner 2011).

Although having frontline defenses against infection would clearly be useful for the maintenance of bodily integrity and for survival, the behavioral immune system is particularly interesting from a psychological standpoint because of its wide-ranging implications for interpersonal and intrapersonal phenomena. These implications rest on certain key principles underlying the functioning of the behavioral immune system. The first such principle is grounded in a classic signal detection dilemma. Accurate perception of pathogen threat is inherently problematic. Outside of medical settings, humans cannot see most disease-causing organisms, and thus people must rely on indirect indicators of their presence. For example, when considering whether a person represents a germ transmission risk, two forms of error are possible. A perceiver may infer that a risk is present when it is in fact not (a false positive error), or a perceiver may infer that a risk is not present when it actually is (a false negative error). In the context of this example, a false positive error is unlikely to be especially costly for the perceiver (e.g., one might not spend much time or effort on social interaction). A false negative error, on the other hand, could lead to direct contact with an infected person and thus transmission of germs to the perceiver. As with many other signal detection problems, the mind has evolved to minimize the more costly perception error. Consistent with this, people commonly presume that more cues indicate the presence of disease threat than is truly the case. This overgeneralization bias is termed the “smoke detector principle” (Nesse 2005)—a smoke detector is designed to sound the alarm whenever it detects smoke (a minor annoyance if no fire exists) and not wait for the presence of fire (which would incur greater damage). Similarly, activation of the behavioral immune system occurs in response to cues that are heuristically, but not necessarily, related to disease threat. For example, people concerned about disease react negatively to many benign cues, including physical abnormalities such as disfigurements, obesity, and

disabilities (Ackerman et al. 2009; Miller and Maner 2011; Park et al. 2003; Park et al. 2007), and membership in outgroups (e.g., being of a different race, nationality, or sexual orientation than the perceiver; Faulkner et al. 2004; Huang et al. 2011). From the standpoint of infection risk, the costs to these reactions are relatively low.

A second key principle highlights the costs associated with activating the behavioral immune system. BIS responses do require energy and effort, although these are often less metabolically draining than physiological immune responses. One way evolutionary processes have fine-tuned these psychological mechanisms to reduce unnecessary costs is by introducing “functional flexibility” (Murray and Schaller 2016). This flexibility refers to the context sensitivity expressed by the behavioral immune system. The BIS is not universally triggered in response to a given cue; it takes into account factors from the proximate context in regulating cognitive, affective, and behavioral expression. Specifically, contextual cues that indicate one has low vulnerability to infection produce relatively little BIS activity, whereas cues indicating one has high vulnerability produce especially strong BIS activity. For example, reactions to pathogen threat can depend on individual differences in perceived vulnerability to disease (Duncan et al. 2009) and on state-based differences, such as being in an early stage of pregnancy, when physiological immune responses are naturally suppressed (Navarrete et al. 2007).

A last important feature of the behavioral immune system is that it includes both avoidance- and approach-based action tendencies. Although pathogen avoidance is the end goal of this system, sometimes the best defense is a good offense. Thus, perceiving infection vulnerabilities may motivate actions intended to resolve those perceived problems. These actions could be as simple as seeking medical or social support, or an increased attraction to signals of safety (e.g., familiar people or objects), but they can also extend to aggressive attempts to remove perceived carriers of disease from one’s environment. For example, chimpanzees encountering another obviously sick or injured chimp may first exhibit

fear (an avoidance reaction) and subsequently perform aggressive displays and attack behaviors (approach reactions) toward that individual (Goodall 1986). In humans, seeing a news report about a flu outbreak may trigger concerns about catching the flu and thus rouse hygienic behaviors. As with chimpanzees, though, stereotypic associations between certain people and disease/disgust can also prompt expression of negative attitudes and aggression toward those people (e.g., gay men; Terrizzi et al. 2010). Therefore, it is useful to construe the behavioral immune system as incorporating the full spectrum of action tendencies that serve the underlying function of preventing infection.

Products of the Behavioral Immune System

Just as the physiological immune system is comprised of many distinct but interwoven biological mechanisms, the behavioral immune system draws on a range of psychological mechanisms in the service of pathogen avoidance. These include emotions, early-stage cognitive processes, preferences, personality dispositions, intergroup attitudes, and behaviors. Emerging research suggests that a diversity of outcomes commonly considered to be deliberative in nature (and thus less influenced by incidental cues such as indicators of pathogen threat), including morality, political attitudes, invention and innovation, and consumer behavior, may also be shaped by BIS processes. Next, several categories of BIS outcomes are reviewed.

In order for the behavioral immune system to function effectively, individuals must detect (true or heuristic) signals of pathogen threat. Much of this detection activity occurs through rapid recruitment of early-stage cognitive processes. For instance, when actively concerned about infectious disease, people focus their visual attention longer on faces with physical disfigurements, even when those features are not true indicators of infection (Ackerman et al. 2009). Further, interpersonal categorization is affected such that perceivers set lenient thresholds for categorizing people along dimensions heuristically linked to disease (e.g., obese weight, old age; Miller and Maner 2012). These biases do not translate into

better memory for individuals, however, because perceivers confuse targets for other targets bearing similar heuristic cues (Ackerman et al. 2009; Miller and Maner 2012). Such effects may be accompanied or driven by the rapid onset of particular emotions, most prominently, disgust (Tybur et al. 2009).

Subsequent to these early-stage processes, a number of forms of interpersonal behavior are influenced by activation of the behavioral immune system. All of these behaviors share the common features of downregulating interaction with people who present relatively higher pathogen risks and upregulating interaction with people who are relatively safe (as with other BIS processes, the cues used to indicate risk or safety are often heuristic in nature). Most generally, chronic and active concerns about infection are associated with lower dispositional extraversion, agreeableness, and openness to experience (Duncan et al. 2009; Mortensen et al. 2010). Together, these traits indicate that people worried about disease exhibit lower sociality. This does not mean that such people simply want to hide from the world, however. Researchers have found that infection concerns are also associated with greater endorsement of social norms and conformity to those norms (Murray and Schaller 2012). Normative behavior requires ingroups with members that adhere to those norms, suggesting that people worried about disease preferentially wish to interact with ingroup members relative to outgroup members. This type of selectivity is found in studies of interpersonal attraction as well. Physical attractiveness is largely based on features indicating health and freedom from infection, namely, symmetry and lack of disfiguring marks (Kurzban and Leary 2001; Murray and Schaller 2016). Behavioral immune activity therefore should attune people to the attractiveness of others and increase the selectivity with which others are judged. Indeed, a number of studies show that people who are chronically or temporarily concerned with infection exhibit exaggerated judgments of attractive and unattractive individuals as well as heightened preference for symmetrical, opposite-sex faces (e.g., Little et al. 2011; Park et al. 2012; Young et al. 2011).

In addition to interpersonal cognition, BIS activation has implications for intergroup attitudes. Much of the research in this area focuses on expression of prejudicial attitudes and discrimination toward groups which are heuristically associated with infectious disease. Such associations can stem from the implicit content of group stereotypes and from a more general neophobia, or fear of the new and unfamiliar, which itself may be grounded in a motivation to avoid exposure to novel and dangerous pathogens (Huang et al. 2011; Kurzban and Leary 2001). For instance, disease concerns both correlate with and cause stronger prejudicial cognitions about physically disabled and obese others (Miller and Maner 2011; Park et al. 2003, 2007). Such concerns also contribute to ethnocentric and xenophobic attitudes, as well as endorsement of behaviors that would limit contact with people from other races or groups (Faulkner et al. 2004; Huang et al. 2011; Navarrete and Fessler 2006; Terrizzi et al. 2010).

Finally, a more recent approach to understanding the broad impact of the behavioral immune system has considered whether cultural attributes and practices may stem, in part, from the threat of pathogen transmission. Much of this work has examined the connection between pathogen prevalence within societies (and their local ecologies) and population-level characteristics. Many of the findings mentioned previously scale up to cultural differences, including preferences for attractive others, traits such as extraversion, and conformist tendencies (Murray et al. 2011; Schaller and Murray 2008). Researchers have also found links between pathogen prevalence and cultural values such as religiosity, political attitudes, and the classic cultural variable of individualism/collectivism (e.g., Fincher and Thornhill 2012; Fincher et al. 2008). More work remains to be done at this level of analysis, but the strong selection pressures exerted by pathogens and parasites along with the wide variety in BIS-linked psychological outcomes suggest that behavioral immune research may yield more exciting insights into many of the commonalities and differences that exist across cultures.

Open Questions in Pathogen Avoidance Research

Despite the breadth of evidence for a suite of psychological pathogen avoidance mechanisms, open questions persist about integration of the BIS with other research areas and on ways of addressing potentially undesirable outcomes of BIS activity. On the latter point, the behavioral immune system appears finely tuned to flexibly respond in the presence of pathogen threats, but it also can produce a number of pernicious cognitions and behaviors that impede social connection, cooperation, multiculturalism, and so on. This is especially problematic if we consider the tendencies of people to overgeneralize perception of cues to pathogen threat and to treat others who represent no such threat as potential sources of germ transmission. For example, the heightened ethnocentrism following disease cue exposure (e.g., Faulkner et al. 2004) may have once served a useful, protective purpose, but in the age of modern medicine, the benefits of avoidance may no longer outweigh the societal costs. Helpfully, though, an understanding of behavioral immune processes offers potential means of controlling such outcomes. If people react by distancing themselves from others perceived to be associated with infection risk in order to mitigate vulnerability to that risk, then interventions to BIS activity could target either those interpersonal and intergroup associative cognitions or the vulnerability perceivers infer in themselves. Some evidence addressing the latter possibility exists. Huang et al. (2011) examined two methods of altering perceived vulnerability—vaccination and handwashing. Whereas recently unvaccinated people expressed prejudicial attitudes toward outgroups following exposure to pathogen threat cues, consistent with work cited earlier (e.g., Faulkner et al. 2004; Navarrete and Fessler 2006), people who had recently received a flu vaccination (and especially people reminded of this event) expressed fewer such negative attitudes. The vaccine conferred some sense of invulnerability to disease, which translated into decreased BIS activity, despite the fact that this vaccine conferred protection only against influenza. A similar effect occurred when people were asked to wash their hands (an even less rational outcome given that

handwashing protects only against current, not future, germ exposure). Research on behavioral immune interventions is sparse, however, and much more work remains to be done.

Another unresolved question with both theoretical and practical importance involves the connection between the behavioral immune system and the physiological immune system. The BIS has the potential to act both as a complementary system, in which behavioral and physiological systems reflect a common underlying immune quality (e.g., as a function of genes, developmental stability, or proximate somatic integrity), and as a compensatory system, in which individuals engage behavioral mechanisms in response to weakened physiological mechanisms and vice versa. Current research does indicate that some degree of compensation occurs between these systems. For instance, during pregnancy, suppression of women's physiological immune functioning is strongest during the first trimester, and this is the same period marked by a high level of behavioral immune activity (e.g., food disgust, ethnocentrism; Navarrete et al. 2007). Other work has shown that when recovering from recent illness, physiological immune efficacy is compromised, and again this period features exaggerated BIS responses (Miller and Maner 2011). An intriguing line of research also suggests that the systems may be complementary as well. Several studies have found that observing pathogen threat cues (e.g., sneezing people) not only activates behavioral avoidance strategies but also may trigger a physiological immune response, perhaps in preparation to fight off infection (Schaller et al. 2010; Stevenson et al. 2011). These investigations are quite new, and often feature relatively small sample sizes, indicating the need for additional research to verify exactly how and when the two systems are connected.

Conclusion

A number of open questions exist about the functioning of psychological pathogen avoidance mechanisms such as those described here. When

do emotions like disgust play a central role in behavioral immune activity and when do they not? How specialized is the behavioral immune system in terms of responsivity to pathogen threat vs. nonpathogenic forms of bodily threat? Should the behavioral immune system be entirely integrated within the larger field of psychoneuroimmunology? Given the active state of research on these topics, such questions may not wait long to be answered.

Definition

A feeling of intense displeasure or revulsion in response to an offensive or revolting object, person, or behavior.

Introduction

An evolutionary perspective on emotions holds that the physiological, psychological, and behavioral characteristics of a specific emotion, such as disgust, should be seen as evolved features that have been useful to humans at some point during our evolutionary history. Individuals equipped with a genetic makeup that enabled them to respond to a certain stimulus or situation by experiencing a certain emotion were better able to cope with and respond to recurring challenges and opportunities and subsequently increased their reproductive success (e.g., Cosmides and Tooby 2000). Seen from this perspective, the advantages that disgust has offered to ancestral humans are likely to have been communicative, motivational, physiological, and influential for future behaviors. In the following paragraphs, the experience and expression,

functions, and individual differences in disgust are discussed, followed by a short conclusion.

The Experience and Expression of Disgust

The emotion of disgust is experienced as a strong feeling of revulsion, often accompanied by nausea, and causing a motivation to withdraw from, avoid, or push away the disgust-eliciting stimulus (Rozin et al. 2000; Oaten et al. 2009). Darwin (1872) considered disgust as one of the six basic emotions: “Disgust [...] refers to something revolting, primarily in relation to the sense of taste, as actually perceived or vividly imagined; and secondarily to anything which causes a similar feeling, through the sense of smell, touch, and even of eyesight” (pp. 256–257). Rozin et al. (2000) argue that from this original toxin-based distaste system aimed to reject tainted foodstuffs, disgust gradually expanded to multiple domains and stimuli and primarily motivates the avoidance of pathogens. In the current literature (e.g., Curtis et al. 2004; Rozin et al. 2000; Oaten et al. 2009; Chapman and Anderson 2013; Tybur et al. 2013), disgust is recognized as playing a key role in motivating behavior that reduces exposure to and contamination with bacteria or viruses.

A feeling of nausea often accompanies disgust and is elicited independently of the ingestion of the disgust-eliciting stimulus, thereby serving to prevent consumption. If such preventative measures fail, vomiting may help to expel the ingested substance. However, although nausea is often seen as the prototypical physiological concomitant of disgust, not all disgusting stimuli elicit nausea. For example, skin-transmitted pathogens such as disease transmission or venom injection via contact with a parasite carrier, venomous insect, or reptile produce a skin-crawling sensation and an urge to protect the skin (the “heebie-jeebies”; Blake et al. *in press*). Additionally, exposure to one’s own and other people’s moral transgressions produces a need for physical cleansing – literally, to wash away one’s sins (Zhong and Liljenquist 2006).

The experience of disgust is accompanied by a typical facial expression which includes slightly narrowed brows, a wrinkled nose, a curled upper lip, and protrusions of the tongue. The wrinkling of the nose restricts airflow through the nose, narrowing the brows reduces the exposed surface area of the eyes, and the curled upper lip and protrusion of the tongue prevent infected substances from entering the mouth (e.g., Rozin et al. 1994). Although different elicitors may cause variations in its expression (Rozin, et al. 1994), the prototypical disgust expression is recognized across cultures (Darwin 1872; Sauter et al. 2010). Brain imaging studies have shown that both experiencing disgust and seeing another person making a disgust face activates the same sites in the anterior insula and to a lesser extent in the anterior cingulate cortex (e.g., Wicker et al. 2003).

The Functional Domains of Disgust

Across cultures, disgust is reliably elicited by stimuli that are associated with the presence of pathogens – such as feces, dead bodies, and sexual fluids (Curtis et al. 2004). This type of disgust, elicited by concrete physical stimuli, is termed *physical disgust* (Chapman and Anderson 2013) or *pathogen disgust* (Tybur et al. 2013). In addition, disgust is elicited by stimuli that are not associated with the presence of pathogens, but rather by abstract social and moral transgressions – e.g., lying, theft, and fraud. This type of disgust is referred to as *moral disgust* (e.g., Rozin et al. 2008; Chapman and Anderson 2013). Its function is to regulate social interactions and particularly to coordinate condemnation and punishment. For some authors (e.g., Chapman and Anderson 2013; Rozin et al. 2008) the transgressions which elicit moral disgust also include certain sexual activities which are condemned by modern society – such as bestiality or incest. However, Tybur et al. (2013) argue that a fully functionalist approach to disgust should take into account the selection pressures which shaped the emotion of disgust, that is, the domains of survival

and reproduction. Thus, in addition to pathogen and moral disgust, *sexual disgust* is thought to be elicited by threats to the functional domain of reproductive success, that is, sexual activities or behaviors which might negatively affect one's long-term reproductive success. The three distinct functions of disgust are detailed further below.

Pathogen Disgust

Pathogens posed a constant threat to survival and reproduction in human ancestral and modern environments. It is likely natural selection favored perceptual systems which could reliably detect those properties associated with pathogen presence (Tybur et al. 2013). Cues to the likelihood that pathogens might be present can be visual (e.g., a slimy texture), olfactory (e.g., the smell of feces), gustatory (e.g., sour-tasting foodstuffs), or tactile (e.g., moisture content). Indeed, cross-culturally, disease-salient stimuli such as unhygienic or ill-looking individuals, bodily fluids (blood, slime, or feces), and skin lesions reliably evoke disgust (e.g., Curtis et al. 2004; Oaten et al. 2009; Tybur et al. 2013). Pathogen disgust is thus thought to have evolved specifically to serve the function of avoiding such sources of infectious agents (Curtis et al. 2004).

Pathogen disgust is sensitive to "false alarms," meaning it is also elicited by objectively non-infectious stimuli such as severe skin burns, amputated limbs, or insects resembling maggots or parasites (Oaten et al. 2009; Park et al. 2003). This bias toward having a relatively low threshold to detect and avoid possibly infectious stimuli is hypothesized to be the result of a cost-benefit computational analysis (Tybur et al. 2013), where the costs of not avoiding a stimulus which does contain pathogens (a type II error, a miss) are higher than the costs of falsely avoiding a stimulus which does not contain pathogens (a type I error, a false alarm; e.g., Oaten et al. 2009). Moreover, such a computational account would also predict that the amount of disgust experienced by certain stimuli is the result of specific trade-offs of avoiding pathogens versus obtaining other benefits (expected value of contact; Tybur et al. 2013).

Indeed, pathogen disgust is moderated by a variety of variables: strangers evoke more disgust than kin (Curtis et al. 2004), and being food deprived decreases the disgust response to unpalatable foods (Hoefting et al. 2009).

Sexual Disgust

Choosing the right mate to reproduce with was – and is – a significant challenge to humans, and choosing wrongly significantly decreases the chances of producing multiple healthy offspring, and as such is reproductively costly. Moreover, the time and energy spent on courtship, copulation, and the raising of offspring are generally restricted to one individual at a time, prohibiting the pursuit of alternative mating opportunities, producing opportunity costs. To avoid these costs, both men and women are choosy about the individuals they mate with and look for high-quality mates. Quality is assessed on various dimensions, most notably on the dimensions of intrinsic quality and genetic compatibility (Tybur et al. 2013). Intrinsic quality can show itself in features that influence objective physical attractiveness (e.g., Grammer et al. 2003), and both men and women assess a possible partner's attractiveness on features like facial attractiveness, body symmetry, and body shape. For example, fluctuating asymmetry is a reliable visual marker for genetic quality and developmental stability (Gangestad and Simpson 2000), and individuals with symmetrical faces are judged to be both healthier and more attractive than individuals with asymmetrical faces. Genetic compatibility can be influenced by genetic relatedness or major histocompatibility complex similarity, and generally humans prefer mates with a genetic makeup that differs from their own. For example, men prefer the smell of MHC dissimilar women compared to MHC similar women (Thornhill et al. 2003).

Low-quality mates might negatively affect one's reproductive success, and sexual disgust is thought to have evolved to stimulate active avoidance of such individuals (Tybur et al. 2013). For most individuals, sexual interactions with an individual with whom we share a significant proportion of our genes – siblings, parents, and

offspring – evoke strong disgust reactions, and sexual relationships between siblings with a history of cosocialization are highly condemned by third-party observers (e.g., Fessler and Navarrete 2004). Additional evidence for a specific function of sexual disgust comes from research showing that disgust and disgust-induced avoidance decrease subsequent sexual arousal, especially in women (Borg and De Jong 2012), and in young males, sexual arousal differentially affects the experience of sexual disgust, but not general disgust (Stevenson et al. 2011).

Moral Disgust

In addition to concrete stimuli-eliciting (pathogen) disgust, abstract moral and social transgressions reliably elicit disgust as well (Chapman and Anderson 2013; Tybur et al. 2009). Moral disgust is elicited by moral transgressions which contain references to pathogens or sexual acts, such as eating rotten meat or engaging in incest. Additionally, this type of disgust is also elicited by transgressions that have no connection to pathogen or sexual disgust, particularly by acts which violate the autonomy and rights of others, and violations or moral rules related to harm or fairness, such as lying, cheating, and stealing (Chapman and Anderson 2013). Individuals who engage in such socio-moral transgressions are often seen as “tainted” or “impure,” making people hesitant to touch them or the objects they have touched and instigating a need for physical cleansing (Zhong and Liljenquist 2006). Moral disgust is experienced by adults as well as young children (Danovitch and Bloom 2009), and brain activation patterns associated with disgust are also visible in a number of moral judgment tasks (Schaich Borg et al. 2008).

An evolutionary account of moral disgust emphasizes that moral transgressions pose direct and indirect costs to individuals and their social groups (Tybur et al. 2009, 2013). From an evolutionary perspective, it would have been beneficial to avoid or punish free riders, rapists, or cuckolds. Moral disgust is hypothesized to facilitate social distancing from and avoidance of individuals who have committed serious moral transgressions (Tybur et al. 2009). Additionally, the facial

expression of disgust functions to broadcast the detection of a violation and may persuade others in one’s social group to condemn the transgressor as well (Tybur et al. 2013).

Individual Differences

Individuals differ in the type of stimuli which elicit disgust as well as the intensity of disgust once it is elicited, that is, they differ in their *disgust sensitivity*. In general, women are more sensitive to disgust than men, and they perceive greater disease threat in disease-related images (Curtis et al. 2004). Women are also more accurate in recognizing the facial expression of disgust, both in male and in female faces (Rotter and Rotter 1988). Although the sexes differ in disgust sensitivity in all three domains, the difference is largest for sexual disgust (Tybur et al. 2009). This sex difference can be explained by the sex differences in the costs and investments associated with reproduction (Trivers 1972). Compared to men, women’s biological investments in offspring are larger, and making poor choices with regard to sexual partners and sexual practices is more costly for women than for men. In order not to jeopardize their chances of producing healthy offspring, compared to men, women are less likely to take sexual risks (e.g., have casual, uncommitted sex; Gangestad and Simpson 2000) and more likely to be disgusted by sexual practices (Tybur et al. 2009).

Moreover, disgust sensitivity has been associated with several personality traits. For example, individuals who are more prone to pathogen disgust also score higher on measures of neuroticism (Olatunji et al. 2012), whereas individuals who are sincere, fair, greed avoidant, and modest are more sensitive to sexual and moral disgust (Tybur and De Vries 2013). In addition, higher disgust sensitivity – in all three disgust domains – is related to lower levels of trait aggression as well as lower daily aggressiveness (Pond et al. 2012). Additionally, higher disgust sensitivity, particularly in the moral domain, has been associated with susceptibility for religious obsessions (Olatunji et al. 2005).

Conclusion

Disgust is a negative emotion, evoking a feeling of revulsion and a desire to distance oneself both psychologically and physically from the disgust-eliciting stimulus. Evolutionary psychologists propose that disgust has three functions, corresponding to domains relevant to human survival and reproduction: pathogen avoidance, sexual decision-making, and condemnation of socio-moral transgressions (see, e.g., Tybur et al. 2013). Individuals differ in the extent to which stimuli elicit disgust and the magnitude of their disgust response. Differences in disgust sensitivity are thought to play a central role in contemporary intra- and interpersonal social processes, such as (obesity) stigmatization (Lieberman et al. 2012).

Disorganized Attachment and Reactive Attachment Disorder

Tommie Forslund¹ and Pehr Granqvist²

¹Uppsala University, Uppsala, Sweden

²Stockholm University, Stockholm, Sweden

Definition

Disorganized-disoriented attachment denotes an insecure category of attachment characterized by an inability to maintain an organized strategy of behavior in relation to the caregiver following activation of the attachment system. Disorganization is thought to stem from an unsolvable approach-avoidance conflict of simultaneously being motivated to approach the caregiver for comfort and being alarmed by the caregiver, a phenomenon termed “fright without solution.” Disorganized attachment has been predicted by abuse and maltreatment and by frightening/frightened behaviors and hostile/helpless states of mind on behalf of the caregiver. Disorganization is behaviorally shown in a variety of fearful, odd, and inexplicable behaviors in relation to the caregiver, including simultaneous or sequential contradictory behavior, freezing and stilling, and direct signs of fear and apprehension of the caregiver. Reactive attachment disorder (RAD) denotes a very rare phenomenon whereby children develop profound difficulties in forming selective attachments to others. RAD stems from a lack of a specific and continuously available

caregiver, is typically observed in children growing up in some institutions, and manifests in two types (inhibited/socially withdrawn and disinhibited/indiscriminately social).

Introduction

John Bowlby, a British psychoanalyst and child psychiatrist (see ► [“John Bowlby: Pioneer of Attachment Theory”](#)), was unsatisfied with the explanations of attachment available at the time, which deemed children’s attachments to their caregivers secondary to other mechanisms, such as children’s drives and/or feeding (see ► [“Psychodynamic Foundations”](#)). Seeking an alternative explanation, Bowlby founded attachment theory by drawing from multiple scientific traditions, most notably ethology, cybernetics, and cognitive theory (see ► [“Evolutionary Foundations of the Attachment System and Its Functions”](#)).

Specifically, Bowlby (1982) argued that humans come into the world endowed with an attachment behavioral system (and attachment behaviors), which function is maintain proximity to caregivers and which was retained through natural selection as it was associated with increased chances of survival against predators and other natural dangers (see ► [“Infant Survival”](#)). Thus, children (the weaker, smaller part) form attachment bonds to caregivers (the stronger, wiser part) who are sufficiently available and responding to their signals (not the other way around; see ► [“Offspring–Parent Attachment”](#)).

Bowlby, having to contest the theories of attachment available at the time, and formulate a new scientifically based explanation, devoted a great deal of effort into the normative aspects of attachment. Although he believed that there are individual variations in the “quality” of children’s attachment, manifested in cognitive affective representations of self and others (termed “internal working models” [IWMs]; see ► [“Individual Variations in Attachment”](#) and ► [“Evolutionary Foundations of the Attachment System and Its Functions”](#); Bowlby 1982), he did not get around to systematizing these variations. Lacking an

empirical method for examining variations in the quality of attachment, he focused his efforts on the need for a continuously available and responsive caregiver and the negative effects following separations from and loss of caregivers (Bowlby 1982).

Attachment theory therefore owes much to his close collaborator Mary Ainsworth and her colleagues and students, most notably Mary Main, for the subsequent mapping of systematic individual differences in attachment quality and organization (Ainsworth et al. 1978; Main and Solomon 1990). Drawing on Bowlby’s ideas about the interaction between the attachment system and other behavioral systems, most notably the exploratory system and the fear system, Ainsworth devised a semi-structured laboratory observation method called the “strange situation procedure” (SSP), which enabled examination of the organization of behavior that children (aged 12–18 months) strike between their attachment needs and those of exploration. That is, the quality of children’s attachments to their caregivers cannot be indexed by any single behavior but is seen in the organization of behavior in relation to the caregiver (see ► [“Individual Variations in Attachment”](#)).

Ainsworth and her colleagues discovered three organized patterns of attachment, varying in quality. Secure attachment is considered the optimal organization of behavior (e.g., of highest quality), due to these children’s ability to use the caregiver as a secure base and a safe haven (see ► [“Secure Attachment”](#)). Insecure-avoidant attachment (e.g., a minimizing strategy) and insecure-ambivalent attachment (e.g., a maximizing strategy) are considered less optimal (e.g., insecure) yet organized patterns (see ► [“Organized-Insecure Attachment”](#)).

Mary Main (Main and Solomon 1990) subsequently discovered a fourth category of attachment, “disorganized-disoriented” (“D”). The display of D behaviors in relation to the caregiver made these impossible to classify using Ainsworth’s coding scheme. Disorganized attachment is discussed below. Reactive attachment disorder (RAD), a very rare clinical condition, is also discussed below.

Disorganized Attachment

Behavioral description. A minority of children from normal populations were impossible to classify using Ainsworth's coding scheme to the SSP, since they, for example, behaved as an avoidant child in one reunion and as an ambivalent/resistant child in the other, or showed inexplicable, bizarre, or fearful behaviors in the presence of the caregiver. Mary Main (Main and Solomon 1990) discovered that children showing these disparate behaviors had one thing in common: an inability to maintain an organized strategy of behavior in relation to their caregiver (hence the label "disorganized"). Disorganization is, as outlined by Main and Solomon (1990), classified through marked displays of any of seven different classes of behaviors: (I) sequential display of contradictory behavior patterns; (II) simultaneous display of contradictory behavior patterns; (III) undirected, incomplete, and interrupted movements and expressions; (IV) stereotypies, asymmetrical movements, mistimed movements, and anomalous postures; (V) freezing, stilling, and slowed movements and expressions; (VI) direct apprehension regarding the parent; and (VII) direct indices of disorganization or disorientation. Thus, D attachment differs from the organized-insecure patterns in the form of a breakdown in behavioral and attentional strategies (Hesse and Main 2000), and D attachment is accordingly even less optimal.

Relational predictors of disorganized attachment and developmental correlates. Mary Main and her collaborator Erik Hesse have theorized that an important antecedent to D attachment is fear in relation to the caregiver and that D attachment follows from frightening/frightened behaviors from the caregiver (Hesse and Main 2000). Disorganized children are, upon activation of the attachment system, thought to become stuck in an unsolvable approach-avoidance conflict of both being motivated to approach the caregiver for protection and support and simultaneously being alarmed by and motivated to avoid the caregiver. The reason for this paradox and why it is unsolvable is as follows: activation of the attachment system triggers a

change in the attachment system's "set goal" (the momentary instruction regarding desired spatial distance to the attachment figure) so that children are motivated to increase the degree of proximity (e.g., use the caregiver as a safe haven), since proximity to caregivers (i.e., the predictable outcome of activation of the attachment system) has been associated with increased chances of survival in our evolutionary environments (i.e., the species-typical functional consequence; see ► ["Evolutionary Foundations of the Attachment System and Its Functions"](#)). However, if children are simultaneously being alarmed by the caregiver (the very object to which the attachment system is programmed to increase proximity), the attachment system receives highly contradictory instructions that it cannot handle (e.g., it cannot settle upon a set goal regarding spatial distance), ultimately leading to a characteristic breakdown in behavior. Being attached and thereby motivated to approach, the caregiver upon activation of the attachment system is therefore a prerequisite for D attachment.

D attachment is common in abused and maltreated children, supporting Main and Hesse's theoretical proposal of fear as key in D (Cyr et al. 2010). However, and in contrast to a common misconception, not all children assigned a D classification have been maltreated. An estimated 15 % of children in normative samples are classified D (van IJzendoorn and Sagi 1999). Indeed, unresolved traumatic experiences in the caregivers can lead to momentary frightening/frightened parenting behaviors in the absence of maltreatment, which in turn predicts D attachment (Schuengel et al. 1999; see ► ["Attachment in adulthood"](#) for a discussion of disorganization in adulthood). Disorganized attachment is the attachment category that shows the strongest association with concurrent and later behavior problems, particularly externalizing problems such as aggression and symptoms of oppositional defiant disorder (see ► ["Effects of Attachment Quality and Organization"](#)).

Temporary overstress, neurological vulnerability, and disorganized behaviors: a word of caution. It cannot be stressed enough that one cannot infer a characteristically disorganized

attachment system merely from observing D behaviors. Research has, for example, found that temporary overstress and neurological vulnerability, such as having early difficulties regulating attention and emotion at birth, are risk factors for disorganized behaviors (Granqvist et al. 2016; Padrón et al. 2014). Thus, children may display D behaviors without these behaviors stemming from a disorganizing relational history.

Reactive Attachment Disorder

Behavioral description. A (small) minority of children do not show clear signs of attachment behaviors in relation to their caregiver and can therefore neither be captured with the main dimensions of attachment quality and organization nor the usual coding scheme to the SSP (Dozier and Rutter 2008). One cluster of children show a marked unresponsiveness to the caregiver in the SSP, neither initiating interactions with the caregiver nor responding to the caregiver's bids for interaction and/or bids to comfort the child. Another cluster of children fail to check back with the caregiver in the unfamiliar setting of the SSP and exhibit a lack of age-typical social reticence by showing a willingness to go off with and approach the stranger as if it were an attachment figure. These patterns are considered two subtypes of reactive attachment disorder (RAD): an emotionally withdrawn/inhibited type and an indiscriminately social/disinhibited type, respectively (Zeanah et al. 2011).

Predictors of reactive attachment disorder.

RAD is mainly found in children who have experienced severe social deprivation, being rare to nonexistent in low-risk samples but among the most common problem found in children who have experienced institutionalization (Zeanah et al. 2011). RAD is therefore thought to stem from a lack of a consistently available caregiver to direct attachment behaviors toward, with a severe lack of species-typical experience compromising the development of the attachment system.

Attachment disorders often remit when caregiving conditions improve, such as following

adoption, attesting to the resilience of the attachment system, but attachment disorders can persevere long after adoption, possibly indicating that the attachment system may have a sensitive period for typical development to occur (Dozier and Rutter 2008). Research to date indicates that the emotionally withdrawn type may be more responsive to intervention than the indiscriminately social/disinhibited type, with children found to display indiscriminate behaviors long after having formed attachment bonds to their foster/adoptive parents (Zeanah et al. 2011). Length of institutionalization and timing of removal also seem important, with children spending more than 6 months in institutional care and being removed from institutional care after 12 months of age significantly more likely to develop problems (Dozier and Rutter 2008; Zeanah et al. 2011).

Conclusion

Disorganized attachment denotes an inability of attached children to maintain an organized strategy of behavior in relation to the caregiver following activation of the attachment system and is predicted by having experienced frightening/frightened behaviors on behalf of the caregiver. However, disorganized behaviors can also be the result of temporary overstress and neurological vulnerability, not representing a disorganizing relational history. Disorders of attachment in the form of profound difficulties forming selective attachments to caregivers, as captured in reactive attachment disorder, are reserved for children who have not had any consistently available caregiver to direct attachment behaviors to, typically children growing up in institutions.

Displaced Reference

Jill P. Morford

University of New Mexico, Albuquerque, NM, USA

Definition

The use of language to refer to entities and events that are spatially and temporally removed from the context of language use.

Introduction

A defining characteristic of human language is the ability to communicate about entities and events that are spatially and temporally displaced from the communicative act (Hockett 1960). Species-typical communication of non-human animals concerns the immediate present. Species-typical communication in humans, by contrast, frequently evokes entities and events

that are unrelated to the context of communication. Human language even allows individuals to refer to purely imaginary and even impossible events. Investigations of this function of human language inform scientific debates about language development as well as the cognitive and social determinants of the human language capacity.

Development of Displaced Reference

The ability to make displaced reference provides enormous evolutionary advantages. Humans can transport their communication partners to any time, place, or mental state with a few well-chosen words. Evidence of this function of human language begins to emerge as early as the first year of life, after infants have achieved essential cognitive and social milestones. Precursors to communicating about the non-present include the ability to form mental representations of entities and events, the ability to engage in joint attention, and the ability to gauge an interlocutor's intentions. Note, however, that each of these so-called precursors is also continuing to change well after the onset of displaced reference.

Comprehension of reference to absent entities develops between 12 and 18 months of age but varies with the stability of the infant's representation of the referent. For example, infants comprehend a reference to an entity that is highly familiar, such as a family member, at a younger age than a reference to a recently introduced stranger. Further, infants respond to a reference to someone who just left the room at a younger age than to a reference to someone who left the room a while ago (Ganea and Saylor 2013). This variable skill stabilizes by the middle of the second year of life.

Production of displaced reference is first seen in requests for absent objects. After several months of reaching, grunting, and whining, toddlers begin using language around 17 months of age to request something they cannot see (Sachs 1983). Sachs painstakingly describes the gradual changes in the use of the word "Where" in parent-child discourse, from parent requests for the child

to point at a present object to the use of the term by either parent or child to initiate a search for an object – either present or absent – to a more sophisticated usage at 22 months in which parent and child simply exchange information about the location of an absent object. Morford and Goldin-Meadow (1997) document a stable pattern of the extension of displaced reference from communication about absent objects to other referential domains. Children move from referring to absent objects, actions, attributes, and locations to talking about the recent past and future and then finally begin to talk about the distant past and future as well as imaginary events. Even deaf children who communicate primarily through self-created gesture systems, called *homesigns*, follow this developmental path, albeit with a delay of a year or more for each expansion relative to children who are learning language from their parents.

Is Displaced Reference a Linguistic or a Pre-Linguistic Capacity?

An ongoing debate about displaced reference as it relates to the origins of human language is whether it is a pre-linguistic, symbolic capacity that preceded the emergence of language or whether displaced reference was only possible by virtue of human language. On the one hand, Liszkowski et al. (2009) argue that displaced reference is a social-cognitive function that may have preceded language in human evolution. They demonstrate that pre-linguistic infants can request an absent object through a pointing gesture, whereas chimps will only point to a location of an occluded object, but not a location previously associated with an object that is no longer there. They argue that chimps lack the human capacity to share common ground with an interlocutor. Further, deaf children without access to linguistic input from their hearing parents can nevertheless make displaced reference with their homesign gestures (Butcher et al. 1991). On the other hand, Cuccio and Carapezza (2015) contend that infants who use pointing gestures may well be preverbal but are not pre-linguistic. By one year of

age, infants comprehend a great deal of language. They argue that when infants produce points with the intention of drawing the interlocutor's attention to the absence of an object, these points are a linguistic and symbolic act that will eventually develop into the ability to express nonexistence and complex negation. Likewise, they argue that homesign systems are an expression of the human faculty for language and, thus, do not provide convincing evidence that displaced reference could have preceded language in human evolution.

While this debate continues, Butcher et al. (1991) point out that even when linguistic modeling of displaced reference is absent, modern day homesigners are surrounded by cultural products that index the non-present – pictures in books of absent objects – and photographs of events the child participated in at other times. Further, homesigners and their parents share social routines that enable them to recognize the referent of nonconventionalized communicative bids. For example, one homesigner was playing with a toy school bus and moving toy figures into the bus. When his mother tried to join his play by enacting their morning routine when she waves good-bye to him, he shook his head at her then gestured that the toys are small, but she and he are both big. He then pointed between his mother and a small Mickey Mouse figurine and then showed how the action figure waved “good-bye!” to the toy children on the school bus (Morford and Goldin-Meadow 1997, pp. 427–428). Hence, while linguistic forms of displaced reference do not need to be modeled for children to devise a way to communicate about the non-present, the symbol-rich and socially structured environments that children inhabit today clearly support the development of this function of human language.

Socializing Children into Displaced Reference

The social dimension of displaced reference is emphasized in research that investigates whether

caregivers' talk influences mastery of this function. Much early research was invested in showing that caregivers' talk about the here and now promotes language development. Specifically, children of caregivers who link their talk very closely to the child's focus of attention tend to develop language more quickly than children of caregivers who persist in talking about something after their child's attention has shifted to something else. Veneziano (2001) points out that a sole focus on the here and now could theoretically inhibit acquisition of the ability to make displaced reference. However, her in-depth investigations of caretaker speech indicate that caretakers actually take advantage of context-linked conversation to introduce displaced reference to their children. While talking about the child's focus of attention, they link the current context to past experience, to potential outcomes that did not happen, to absent entities, and so forth. More than a third of utterances that are focused on the here and now nevertheless reference a displaced entity or event.

Between 30 and 36 months of age, typically developing children begin initiating talk about the past and future. Parents scaffold their children's participation in such conversation, raising their expectations of their children's contributions as they become more linguistically adept (Lucariello and Nelson 1987). Fivush and Nelson (2006) show how conversation about the past is fundamental to the child's developing conception of self and to the discovery that representations of past events are distinct from one person to another. In this way, there is a dialectic between the use of displaced language and an individual's representation of past and present. Likewise, for parent-child talk about imaginary topics, which begins at a similar age, there is a strong interplay between engagement in displaced fantasy talk and the development of cognitive abilities including creativity, decision-making, and self-regulation. As Sachs (1983, p. 25) concludes, adults “do not deliberately structure their language to teach, but in the course of quite ordinary everyday talking, they use what the child already knows to provide opportunities for the child to learn something new.”

Conclusion

The ability to refer to the non-present is a hallmark of human language. Development of this function of language emerges in the earliest stages of verbal interaction, but with considerable support from caregivers. Scientific investigations of the development and use of displaced reference reveal that cognitive, social, and linguistic skills interact in complex ways to allow humans to evoke the non-present in the minds of others.

Disposable Soma Theory

Lukas K. Sotola

Western Illinois University, Macomb, USA

Iowa State University, Ames, IA, USA

Synonyms

[Evolutionary theory of aging](#); [Trade-off between reproductive fitness and longevity](#)

Definition

Organisms must devote limited resources either to produce more offspring or to live longer. Evolutionarily, it is beneficial to sacrifice the latter for the sake of the former.

Introduction

Senescence is the decrease in an organism's ability to reproduce and the increase in the chances it will die as it ages. Explaining why senescence evolved at all has long been an issue for evolutionary theory, because any decrease in an organism's ability to reproduce should be selected against, and senescence – which always ends in death – completely eliminates reproductive potential and occurs in all organisms. Disposable soma theory (DST) was first proposed by Kirkwood (1977) as an evolutionary explanation for this. It posits that a trade-off between reproductive fitness (i.e., an organism's ability to produce offspring) and longevity (i.e., the number of years an organism lives) is what causes aging. Organisms must divide limited energy resources between reproduction and maintaining their bodily tissues (i.e., somatic maintenance). Theoretically, an organism could devote

all of its energy to preventing aging and live forever, but because most animals in the wild die from extrinsic causes (e.g., being preyed upon, dying of infectious disease, etc.), preventing aging would not benefit organisms, because it is likely that they would still die of non-age-related causes even in the absence of aging. It is therefore adaptive to devote only the minimal amount of energy needed to reach the average life expectancy of their species in the wild (which is set by levels of extrinsic mortality) and to devote the remaining energy to reproduction. This reduction in energy focused on somatic maintenance which causes defects in the replication of cells, which with time accumulate enough so that they become harmful. After many years, this leads to aging and eventually death. This is what the DST proposes causes aging (Kirkwood and Rose 1991).

An Example from Kirkwood (1977)

As an example, given that the vast majority of deaths in the wild are due to extrinsic mortality, an organism might be a member of a species whose average life expectancy in the wild is 20 years. This organism could theoretically invest enough resources in somatic maintenance such that it would never age, but this would mean that it would have almost no resources to devote to reproduction. This would destroy its ability to pass on its genes, which is maladaptive, and would not reduce its chances of extrinsic mortality (e.g., even if an organism does not age, it can still be preyed upon, etc.). Therefore, it would be beneficial for the organism to reduce its level of somatic maintenance to such a level that it would die of old age at a maximum of 20 years old. This would allow it to reproduce more while not truly reducing its longevity. Thus, DST predicts that the rate of senescence should increase with increases in extrinsic mortality.

Gender Differences in the Trade-Off Between Fertility and Longevity

According to DST, there should be sex differences in the relationship between longevity and

reproduction. Both sexes experience costs to reproduction, but the nature of the costs differ. Females experience more direct costs from reproduction than males, because females must carry children for several months, experience the trauma of childbirth, and use additional energy for creating milk. Therefore, the decrease in longevity for females for each additional child should be greater than that for males, whose cost for reproduction is mainly seeking mates and fending off rival suitors (Chereji et al. 2012). Travers et al. (2015) found this in female *Drosophila melanogaster*, a species of fruit fly; Nussey et al. (2006) found this effect in red deer, and studies on archival data of the number of children and age of death of seventeenth and eighteenth century aristocracy have found that number of children was negatively correlated with age of death (Chereji et al. 2012).

However, males also face a greater challenge in passing on their genes. Although males have a greater chance to pass on their genes to a huge number of offspring, owing to the fact that they can easily impregnate many females, they also face greater competition from other males (i.e., intrasexual competition). Therefore, it is also more likely for males to fail to reproduce due to intrasexual competition. Thus, it is common for males to pursue “live fast, die young” strategies as seen in higher levels of risk taking. This may cause selection for a shorter life span on average for men, because of the accumulation of wear and tear on their tissues at a greater rate than females. Females, on the other hand, have much lower levels of intrasexual competition and therefore much less variability in how many offspring they have; that is, there is a great chance that any given female will have at least a moderate number of offspring. Therefore, females tend to pursue lower-risk strategies for mating and child-rearing, and this would lead to selection for longer life span. In summary, females should experience a greater decrease in their longevity with each additional child, while males’ general longevity is shorter due to intrasexual competition (Bonduriansky, Maklakov, Zajtschek, & Brooks, 2008).

The Effect of Mating Cost and the Abundance of Food

Using a mathematical model, Shokhirev and Johnson (2014) investigated the combined effects of the rate of extrinsic mortality and mating resource costs on senescence. They found that when mating costs are high but energy (e.g., calories) is abundant in the environment, an increase in the rate of extrinsic mortality increases average longevity. This is because when the mating costs are high and extrinsic mortality increases, the population decreases, because for a species to reproduce at a rate that will keep up with the reduction due to the increase in extrinsic mortality when mating costs are high will be immensely difficult (due to the costs). But this means that there is more energy available for each organism that does survive due to the decrease in the population, which allows them to devote more time to accruing resources and makes it easier to avoid extrinsic mortality. Furthermore, this increase in available resources allows individuals to obtain a lot of energy resources before reproducing. This will reduce the rate of death from intrinsic causes (e.g., aging), meaning the organisms should invest more in the repair of their tissues, thereby decreasing senescence and increasing longevity.

When mating costs little energy and when little food is produced, an increase in extrinsic mortality will decrease longevity in a species. Shokhirev and Johnson (2014) speculate that this is likely because, when there is little food and mating is easy (i.e., does not cost much energy) and extrinsic mortality increases, organisms begin to spend more time on mating (because it is easier) and less on acquiring food and maintaining bodily tissues. This then leads to the accumulation of tissue defects, which leads to rapid aging.

Life History Theory and the Disposable Soma Theory

DST can be further understood in the context provided by life history (LH) theory. LH theory deals with how organisms allocate time and energy to tasks and traits in ways that maximize

fitness (Del Giudice, Gangestad, & Kaplan, 2015). One of the fundamental trade-offs is between present and future reproduction. According to LH theory, growth is the process by which organisms increase how much energy they store, which increases their life span and their future potential for reproducing by virtue of the years that they add to their life span. Maintenance is the process through which organisms repair tissues and devote energy to keeping their immune system functioning. Reproduction is the process of creating offspring. How organisms balance these three processes is referred to as LH strategy. The loss in future reproduction potential and the loss in life span caused by current reproduction are called the cost of reproduction. The optimal amount of energy organisms should devote to maintenance decreases as the quantity of tissue of an organism (i.e., as it grows from infancy to adulthood) increases, because maintenance becomes ever costlier. Furthermore, in the case of the aforementioned “life fast, die young” strategy that males ought to pursue, the greater investment males put into intrasexual competition over mates means that they will have less energy to devote to maintenance, which causes them to age faster than females. So although female longevity should decrease to a greater extent with each additional child, males will generally age more rapidly.

Challenges to the Disposable Soma Theory

There is much compelling evidence for DST in nonhuman animals, but results are mixed when applying DST to humans. DST predicts that the more children humans have the earlier they should die; however, many studies have found no such effect – or a reverse effect – and many of the studies corroborating this prediction have not been methodologically sound. For example, one study looked at the relationship between number of children and longevity in British aristocrats born between the seventeenth and nineteenth century. But other researchers have pointed out that much of those data are inaccurate and that

the sample is not representative due to the great wealth of the aristocracy. Furthermore, Chereji et al. (2013) found, in a sample of 15,622 twins, that having children *increased* longevity. Moreover, Gavrilova and Gavrilov (2005), in a review of past literature on the relationship between fertility and aging in humans, found that the *majority* of studies done on humans have found a positive correlation between fertility and age at death. Furthermore, Gavrilova and Gavrilov (2005) did their own study in which they looked at the life span of people who had no children at all and found that childlessness had no predictive value for the age at which women would die. Finally, it is impossible to conduct an experiment on humans with regard to the DST, as it would be unethical; thus, it is impossible to ever know for certain whether DST applies to humans in a direct way.

Conclusion

DST states that aging occurs as a result of the trade-off between devoting energy to tissue maintenance and reproduction. Because it is evolutionarily beneficial to direct energy away from maintenance to reproduction, this allows tissue defects to build over the years, eventually leading to aging. DST remains an influential evolutionary theory of aging. However, results have been mixed when researchers have tried to find evidence of its applicability to humans. Future research is needed to find whether the mathematical model of Shokhirev and Johnson (2014) and LH theory's predictions can be reconciled with studies of the relationship between fertility and longevity in humans that find no correlation or even a negative correlation between the two variables.

Disruptive Coloration

Changku Kang and Thomas N. Sherratt
Department of Biology, Carleton University,
Ottawa, ON, Canada

Synonyms

Disruptive camouflage; Disruptive pattern

Definition

Disruptive coloration is a set of high contrast markings that creates false edges and boundaries and thereby hinders the detection or recognition of an object's true outline and shape.

History and Mechanisms

Disruptive coloration is a camouflage technique in which concealment is attained using high contrast markings. These markings create false edges inside an object and/or obscure existing ones, and thereby disrupt the detection or recognition of the object's true outline. Thus disruptive coloration combines two methods of concealment: (i) creating the appearance of false edges and boundaries within an object and (ii) concealing the real object boundary (Stevens and Merilä 2009).

Disruptive coloration is seemingly widely employed in animal kingdom, and the approach has been exploited in a variety of fields including the military and art. Although the phenomenon was eluded to by the prominent naturalist the Henry Walter Bates, disruptive coloration was formally recognized and described by artist and natural historian Abbott H Thayer (1909), in his book *Concealing Coloration in the Animal Kingdom* (page 77):

“Markings... of whatever sort, tend to obliterate, – to cancel, by their separate and conflicting pattern, the visibility of the details and boundaries of form...”

Thayer's principle of “ruptive coloration” influenced the design of camouflaged military uniforms and vehicles during World War I.

In 1940, a British zoologist Hugh B Cott expanded the theory of disruptive coloration and classified several mechanisms that organisms employ to achieve disruption of edges in his book *Adaptive Coloration in Animals* (Cott 1940):

- (1) “Differential blending” arises when some color patches in an animal have the same color as their background while the other patches stand out, which blends the animal outlines into background and creates the false boundaries (Fig. 1a).
- (2) “Maximum disruptive contrast” predicts that highly contrasting, thus seemingly conspicuous, patterns between adjacent patches within an animal actually conceal by disruptive effect (Fig. 1b).
- (3) “Coincident disruptive coloration” conceals characteristic features, such as eyes or limbs, by having the color patterns on different, but adjacent, body parts aligned to match those features (Fig. 1c).
- (4) “Disruption of surface through false edges” works by breaking up the continuity of outlines through markings that are touching the animal outline and thereby make “gap on the surface” which creates the false outlines of non-regular shapes (Fig. 1d).

Several of Cott's principles were rigorously tested in the early twenty-first century by exposing disruptively patterned (or otherwise patterned for comparisons) artificial moth-like targets to birds under field conditions and estimating their “survivorship.” This artificial moth prey system has provided empirical support for Cott's principles and revealed that concealment through disruptive coloration can be attained mainly via the color patterns that touch the outline of animals, while highly contrasting colors enhance this effect (Cuthill et al. 2005; Stevens et al. 2006). Subsequent eye-tracking experiments with human subjects showed that computer generated moth targets with more edge-intersecting patches were looked at for longer periods prior to attack, and passed-over

Disruptive Coloration,

Fig. 1 Examples of subprinciples of disruptive coloration: (a) differential blending, (b) maximum disruptive contrast, (c) coincident disruptive coloration, and (d) disruptive of surface through false edges (All photos adapted from Cott (1940))

more frequently during search tasks (Webster et al. 2013).

Although disruptive coloration is a conceptually different mechanism from background matching (which is a widespread camouflage mechanism achieved by the resemblance in color and patterns with the object's background), they are not mutually exclusive and animals often use both background matching and disruptive coloration simultaneously. Indeed, since some of the principles of disruptive coloration (e.g., differential blending) require the color matching between an object and its background, disruptive coloration seldom occurs alone, but usually accompanies (or requires) background color matching to give disruption effect. Nevertheless, the adoption of disruptive coloration can sometimes involve a trade-off in which high contrast

marks reduce the probability of an object being detected, even at the expense of reduced background matching (Webster et al. 2013). Moreover, background matching can achieve camouflage without disruption effect, particularly on uniform surfaces (see Fig. 1b).

Many animals have disruptive patterns that have evolved for camouflage including isopods, frogs, butterflies, birds, avian eggs, and cephalopods. One of the best examples of disruptive patterns can be found in cuttlefish. Notably, cuttlefish dynamically change their body patterns dependent on their visual background: they adopt disruptive patterns only when they are against highly contrasting visual backgrounds while, when they are against a plain background, they adopt uniform/stipple patterns (Hanlon et al. 2009). This suggests that disruptive patterns may be more

effective ways for camouflage against visually complex/contrasting backgrounds while background matching can be effective against plain backgrounds.

Conclusion

Disruptive coloration is a form of camouflage that prevents detection and (or) recognition by breaking up the true outline of an object through conspicuous internal contrasting patterns. This camouflage mechanism is widely used in many animals and adopted in many disciplines such as art and military services.

Disruptive Selection

Alan H. Krakauer

University of California, Davis, Davis, CA, USA

Synonyms

[Divergent selection](#)

Definition

A mode of selection in which individuals with extreme trait values have higher fitness compared to those with intermediate values.

Introduction

Although the popular view of natural selection evokes directional change – bigger, faster, smarter, more colorful – there are modes of selection that can lead to evolutionary change of a trait without directional shifts in its distribution. One example of this is disruptive selection, in which individuals with trait values close to the mean have lower fitness than those exhibiting more extreme values. Disruptive selection can lead to a bimodal distribution of trait values and therefore can result in an increase in the variance of a trait without a change in its mean.

Disruptive selection, also known as diversifying selection, refers to a selective regime in which extreme values have higher relative fitness than values closer to the mean. In a population genetic context in which a trait is influenced by a single locus with two alleles, disruptive selection would occur when there is underdominance – i.e., if both homozygote genotypes have higher fitness than the heterozygote genotype. Underdominance can lead to an unstable equilibrium, with one allele

typically going to fixation (Fisher 1922; Wright 1931), unless additional factors such as negative (i.e., inverse) frequency-dependent selection or interactions with other genetic loci can increase the relative fitness of the less common homozygous genotype.

Continuous traits under the influence of multiple loci can also experience disruptive selection. In these cases, intermediate forms are less competitive than (i.e., have reduced fitness compared to) forms at the extremes of the trait distribution. Provided the trait is sufficiently heritable, disruptive selection can lead to trait divergence (Fig. 1). Several examples are briefly reviewed below.

Disruptive Selection, Fig. 1 disruptive selection over time, with the frequency of a particular value of a phenotypic trait (solid line) and selection (depicted as relative fitness, dashed line). In panel a, the unimodal trait distribution before selection has acted. Initially, selection will likely cause the trait distribution to broaden with increased variance around the mean (panel b). Over repeated episodes of disruptive selection, the trait may assume a bimodal distribution (panel c)

Divergent selection on gamete size: Anisogamy refers to a species producing gametes of different size (e.g., small sperm and large eggs). Many models exploring the evolution of anisogamy rely on disruptive selection to explain the transition from isogamy (gametes of uniform size). In one formulation of the model, imagine cumulative gamete size determines zygote survival with a diminishing returns function (larger gametes survive better, but an increase in size has more of an effect on small compared with large zygotes). Additionally, reproducing individuals have a set amount of resources they can dedicate to gamete production, such that gamete size trades off against the number of gametes produced. If a population starts out as isogamous with intermediate-sized gametes and if gametes compete against other gametes for fertilization, models predict that the population should eventually evolve to a bimodal distribution of gamete sizes. Individuals that make lots of small gametes will be favored because of increased fertilization success, while individuals who make very large gametes will also be favored by ensuring their offspring are competitive. Individuals who make intermediate-sized gametes will lose on both accounts (Lehtonen and Kokko 2011; Parker et al. 1972).

Disruptive Selection for Avian Plumage Maturation: A classic example of disruptive selection has been found in behavior and plumage brightness in a small songbird, the Lazuli Bunting (*Passerina amoena*) (Greene et al. 2000). Males in their first breeding season show a bimodal distribution of fitness based upon plumage brightness, with males of intermediate brightness exhibiting reduced fitness. Brighter males were able to claim high-quality territories of their own, while duller males were sufficiently non-threatening that older territorial males permitted them to settle nearby. These older males apparently benefit by using the young, dull males as buffers against nearby older competitors seeking extra-pair copulations. Males with intermediate plumage brightness were unable to settle on good territories by means of either of the above routes and had the lowest mean reproductive success of any males in their age class.

Ecological Character Displacement: Disruptive selection is thought to play a role in generating and maintaining much of observed phenotypic diversity we see. Ecological character displacement results partially from frequency-dependent competition for resources. For example, some lake-dwelling populations of three-spined stickleback fish (*Gasterosteus aculeatus*) show intraspecific trophic and habitat specialization; lakes can host morphologically and behaviorally distinct benthic and limnetic forms. The two forms can interbreed, yet in field experiments, Bolnick and Smith (2004) found that when fish density was increased, forms with intermediate morphology appeared to face a fitness cost when experiencing the increase in competition. These intermediate forms had smaller body size and relative gonad size compared to conspecifics with more typical benthic or limnetic morphology, a pattern also found in many natural populations (Bolnick and Lau 2008).

Reproductive Character Displacement: Reproductive character displacement occurs when isolated populations experience secondary contact and selection acts on traits related to mating or fertilization success. For example, consider two species of chorus frogs (*Pseudacris feriarum* and *P. nigrita*); secondary contact has led to sympatric populations in which the two species interact. These species show character displacement in male call attributes, with call pulse rate and/or pulse number of *P. feriarum* differing between populations depending on whether they are sympatric with *P. nigrita*; female preferences of the rarer of the two species also differed in sympatric compared with allopatric populations (Lemmon 2009). Furthermore hybrids suffered substantial fitness reduction compared with non-hybrid offspring. The majority of the fitness cost could be attributed to female preference for species typical calls rather than the intermediate calls of hybrids (Lemmon and Lemmon 2010). Thus disruptive selection, in this case against hybrids in the hybrid zone, can explain much of the observed diversification in reproductive traits between these two species.

Conclusion

Selection can take a variety of forms, and fitness functions may not be limited to any one of the primary modes (directional, disruptive, or stabilizing). For example, selection could be simultaneously directional (increasing or decreasing the mean) and also stabilizing or disruptive (changing the variance). Disruptive selection is an important driver of diversification, particularly for generating diversity within a population. As such, it is responsible for many of the dazzling array of adaptations we see in the natural world.

Distinguishing the Direction of Sounds

Michael Khalil
University of Nicosia, Nicosia, Cyprus

Synonyms

[Sound generation](#); [Soundwaves direction](#); [Transmission of sound](#)

Definition

The way the sound is directed.

Introduction

To better comprehend the direction of sound, we must consider how sound is directed. When sound is traveling through the air it eventually reaches the ear; there is where all the processing

The Direction of Sound

Sound is generated when an object vibrates and creates soundwaves traveling through the air as a pattern of pressure changes heard as sound (Moore 2001). Air is one medium for the traveling sound to be heard. According to the pressure of the environmental medium (called impedance), the associated pressure will be needed for the soundwave to travel (see Pickles 2012, pp. 1–19). Specifically, when the molecules of the air are drawn together, pressure is generated leading to a process named compression. When the opposite happens, the pressure from the molecules decreases, leading to a process named rarefaction (Oghalai and Brownell 2012). Sound is described in sinusoids, and each sinusoid is called a Fourier component of the sound – based on a theorem by Fourier. A magnitude plot of the components based on frequency is described as a spectrum. Fourier analysis of sound is to produce the spectrum of the soundwaves by slicing the waveforms to sinewaves of various frequencies (Moore 2001; Pickles 2012). In each soundwave, there are two variables: frequency (number of waves measured in hertz) and intensity or loudness (magnitude of movements formed measured in decibels).

Hearing the Traveling Sound

Once sound is generated, our outer ear captures the soundwaves which reach the eardrum, causing it to vibrate. The structures of the middle ear are then activated, that is, the ear bones transform the vibrations into fluid-borne vibrations in the cochlea, activating the structures of the inner ear

to transform the soundwaves into bioelectric signals in the auditory sense cells (Hoy 2012). Sound is then analyzed into the structures of the inner ear, using spectral and temporal analyses. Spectral analysis is used to extract and define the frequency components of the acoustic information. This is done inside the cochlea, where the amplitude and temporal components of the sound is analyzed. This constitutes the first processing of auditory information, with further processing happening in the auditory pathway to the brain (Seikel et al. 2010).

To distinguish between high and low sounds, the basilar membrane closer to the vestibule is vibrated. This structure is the basal end of the cochlea. The basilar membrane is responsible for the analysis of sound frequencies as demonstrated by a series of experiments by von Bekesy (1948). The low frequency sounds are processed in the apex of the basilar membrane. The traveling wave always travels from the base to the apex of the basilar membrane according to the membrane gradient (Seikel et al. 2010).

Localization of Sounds

The location of sound is based on the process of a binaural hearing, in which the sound is analyzed by the central auditory pathways from the auditory information that were sent by the two cochleae to the hearing structures of the brain. Consequently, there is a process of segregation and localization of the sound signals in order to separate the acoustic messages from noisy environments (see Moore 1991). There is an evolutionary advantage for this type of hearing that lead to the survival of species (Avan et al. 2015). Binaural hearing take place at three levels of the brain: the Superior Olivary Complex (SOC), the Nuclei of the Lateral Lemniscus (NLL) and the Inferior Colliculus (IC) (see Moore 1991).

Conclusion

The direction of sound moves from a vibrating object to produce soundwaves through a medium,

usually the air. According to the frequency (i.e., number of waves measured in hertz) and the intensity (magnitude of movements formed measured in decibels) the sound is directed to the structures of the middle ear, through the structures of the outer ear. The sound then travels to the structures of the inner ear and the auditory areas of the brain for further analysis along with the aid of binaural hearing process.

Docosahexaenoic Acid (DHA)

Nikki Clauss and Ashley Rankin
Oklahoma State University, Stillwater, OK, USA

Synonyms

[Essential fatty acids](#); [Omega-3 fatty acids](#)

Definition

Docosahexaenoic acid (DHA) is one of the major polyunsaturated fatty acids and a metabolite of the omega-3 family fatty acids. DHA is the most prevalent polyunsaturated fatty acid in the central nervous system, located in the membrane phospholipids of the mammalian brain, particularly in the phosphatidylethanolamine portion of cell membranes, and retinal cells. DHA accounts for 40% of the membrane phospholipid fatty acid in the brain and is found at rates of more than 30% in the whole retina and up to 60% in the discs of the rod photoreceptor cells. DHA is a very long-chain fatty acid, made up of a 22-carbon backbone and six double bonds. The large side chain and a high degree of unsaturation are properties that appear to grant properties to cell membrane phospholipids that are unique in function and structure, particularly to those in the retina and neuronal synapses in the brain.

Introduction

Neurons are not able to metabolize DHA in vivo, so they must make use of dietary omega-3 fatty acid. The diet of Paleolithic humans was characterized by a relatively equal amount of omega-6 and omega-3 polyunsaturated fatty acids (Crawford 1968). This balance is important because it protects against inflammation, which in turn is helpful in terms of gene expression, the metabolism of leukotriene and prostaglandin, and the production of interleukin-1 (IL-1; Simopoulos 2008). The excessive consumption of omega-6

fatty acids, such as arachidonic acid, is one factor leading to an imbalance between omega-6 and omega-3 fatty acids. In this instance, not only are omega-6 fatty acids being consumed in greater amounts than omega-3 fatty acids, but arachidonic acid also displaces DHA from membrane phospholipids, reducing plasma DHA levels.

Over a short period, significant changes in the human diet have occurred, creating a new phenomenon in human evolution. The western diet is now characterized by disproportionate consumption of omega-6 fatty acids, and it is estimated that the majority of individuals in these regions are DHA-deficient (Simopoulos 2008). The agricultural era is one contributor to the decrease in omega-3 polyunsaturated fatty acids. Because livestock is largely fed an omega-6-rich diet of grain, their carcasses contain far less omega-3 polyunsaturated fatty acids than they would if the animal consumed grass. In comparison, wild animals that feed on wild plants are very lean and contain much more polyunsaturated fatty acids than that of domesticated livestock (Crawford 1968). The difference in omega-3 content between wild and cultivated fish and chicken eggs has also been detected (Raper et al. 1992). Public fear of saturated fat and subsequent government recommendations to substitute vegetable oils (omega-6 fatty acids) in their stead has also become a contributor to low DHA consumption in western populations.

Because the advice to consume more vegetable oil is inconsistent with human evolution, it may lead to maladaptation in those genetically predisposed (Simopoulos 2011). Suboptimal consumption of omega-3 polyunsaturated fatty acids, especially DHA, leads to increased inflammation and is correlated with many diseases common in the western world (i.e., coronary heart disease). For example, deficiencies in alpha-linolenic acid, a precursor to all omega-3 polyunsaturated fatty acids, lead to a slew of symptoms that include paresthesia, blurry vision, leg pain, general weakness, and an inability to walk (Holman 1971).

DHA is crucial for brain development. The developmental period from birth to 2 years of age is when humans experience the greatest brain growth, in which DHA plays a major role.

DHA is known to affect neurotransmitter pathways, synaptic transmission, and signal transduction (Carver et al. 2001). It has a unique structure, including multiple double bonds, which allows DHA to increase the effectiveness of cell signaling. Levels of DHA in the neural membrane impact the maturation of cortical astrocytes, as well as cortical glucose uptake and metabolism. Importantly, myelination of the frontal lobes continues throughout childhood and adolescence, and DHA is vital to this growth (Brown and Jernigan 2012). The frontal lobes are not only rich in DHA, but are also responsible for cognitive processes such as planning, problem-solving, and focused attention (Anderson et al. 1998). Indeed, there is evidence that a child's IQ is increased for every 100-mg increase of maternal DHA (Cohen et al. 2005).

DHA and the Evolution of the Modern Human Brain

Given the importance of dietary DHA in the central nervous system, the discovery of high quality and easily digested nutrients from marine sources is likely to have been an important turning point in human evolution (Newman 2001; Bradbury 2011). Using fossil records combined with stable isotope values of the bone collagen of human remains allows for an estimate of the proportion of protein attained in the diet from aquatic versus terrestrial sources in the 10 years before death (Richards et al. 2001). This technique provides evidence that the Neanderthals main source of protein came from land-dwelling creatures such as wolves and hyenas. These food sources would have had very low levels of alpha-linolenic acid or DHA. There is no sign of aquatic-based protein being part of the Neanderthals diet according to their bone collagen samples. In contrast, there is evidence that early modern humans made aquatic-based protein a staple of their diet. Aquatic sources of protein accounted for between 10% and 50% of the diet, depending on the region to which the sample was attributed. This marked increase in consumption of aquatic sources coincided with a rise in the use

of crafts, such as personal ornamentation, pottery figurines, and textiles (Bradbury 2011). It also coincided with the rapid expansion of gray matter in the cerebral cortex (Broadhurst et al. 2002).

DHA and Sexual Selection

The rapid expansion of brain size in the modern human is likely to have been accompanied by other changes in processes to support the development of such a large brain. Given the incredible importance of long-chain polyunsaturated fatty acids in neurodevelopment, adaptations to acquire, store, and appropriately invest such a resource emerged in females (Lassek and Gaulin 2008). This is apparent in the sexually dimorphic nature of fat storage. Human females tend to have higher gluteofemoral fat stores than human men, and gluteofemoral fat is a main source of long-chain polyunsaturated fatty acids, DHA in particular. Further, abdominal fat appears to have a negative effect on the availability of the essential fatty acids that are essential for infant brain development.

The fact that lower-body fat *increases* the supply of neurodevelopmental resources, such as DHA, and upper-body fat *decreases* these resources is an indication that a low waist-to-hip ratio is an important evolutionary trait. Indeed, a lower waist-hip ratio is correlated with higher blood-DHA levels (Karlsson et al. 2006), and the majority of long-chain polyunsaturated fatty acids found in human breast milk come from maternal fat stores instead of maternal diet (Del Prado et al. 2000). Women's waist-hip ratio is also negatively associated with her own and her offspring's cognitive ability (Lassek and Gaulin 2008). Because of this, the essentiality of DHA for early brain growth, and the human evolutionary history of rapid brain expansion, it is possible that there was once a considerable demand for these brain-building resources, creating a male preference for lower waist-hip ratios. In fact, there is substantial evidence that waist-hip ratio is a significant gauge of female attractiveness, as indicated by a strong

male preference for lower waist-hip ratios in potential sexual partners (e.g., Singh 1993; Tovee et al. 2002; Wilson 2005).

Impact on Animal Behavior

There is evidence that omega-3 polyunsaturated fatty acids play a major role in animal neural development and behavior. When rats that are fed diets rich in DHA for two generations, they produce offspring that respond correctly to a cognitive task at significantly higher rates than the offspring of rats that are fed DHA-deficient diets for two generations (Yamamoto et al. 1987). Similarly, feeding either DHA-deficient or DHA-enriched diets to mouse mothers and their offspring produces significant changes in the ratio of omega-3 to omega-6 brain phospholipid acetyl chains, and these changes lead to changes in performance on learning and memory tasks (Nakashima et al. 1993). For example, compared to mice fed diets high in linoleate oil (source of omega-6 fatty acid), mice fed diets high in alpha-linoleate oil (precursor to omega-3 long chain polyunsaturated fatty acids DHA and eicosapentaenoic acid) were able to reach a safe platform in a water maze test significantly quicker than linoleate oil-fed mice, and they outperformed the linoleate oil-fed mice in an elevated plus maze task. These mice also demonstrated differences in sensitivity to drugs that are known to affect behavior, such that the linoleate oil-fed mice demonstrated a significantly higher degree of sensitivity to an anesthetic and scopolamine injections than the alpha-linoleate oil-fed mice did. Further, DHA has been shown to play a protecting role in the impact that prenatal stress typically has on learning and cognitive development in mice. For example, pregnant rats that experience restraint stress tend to produce offspring with cognitive impairments, among other problems (Feng et al. 2012). However, if pregnant rats are fed DHA-rich diets, the negative impact of restraint stress is buffered. Therefore, DHA appears to play a role in preventing prenatal stress-induced brain dysfunction in animal models.

Impact on Human Behavior

DHA also appears to play a role in human cognition and behavior, beginning in the earliest days of infancy. Evidence suggests that early infant sleep/wake patterns are an indication of the functional expression of the central nervous system and are highly correlated with future behavioral outcomes. A significant relationship between prenatal DHA consumption and infant sleep/wake cycles has been demonstrated. Infants whose mother took a 300 mg per day DHA supplement had more stable sleep-wake cycles within the first 2 days of parturition than infants whose mothers received a placebo (Judge et al. 2012).

In contrast, self-reported low or no prenatal consumption of fish is associated with subsequent offspring deficiencies in communication skills, verbal IQ, fine motor skills, and social communication (Hibbeln et al. 2007). The same associations are not seen among the offspring of mothers who report consuming three or more servings of fish per week while pregnant. Similar deficits were found among the offspring whose mothers had low blood-DHA levels at the time of birth, as measured by cord blood (Kohlboeck et al. 2011). Importantly, mothers with high blood-DHA levels produced offspring who scored higher on measures of cognitive ability, but the effect dissipated after age seven.

Lower omega-3 polyunsaturated fatty acid blood levels have been linked to depression. In young boys (ages 6–12), low blood plasma phospholipid levels of omega-3 polyunsaturated fatty acid are associated with more behavior problems, temper tantrums, and sleep problems than their normal-DHA-level counterparts (Stevens et al. 1996). Similarly, another study demonstrated that college students who took DHA-rich oil capsules for 2 months during a particularly stressful time in the semester were significantly less aggressive than college students who took a placebo during the same timeframe (Hamazaki et al. 1999). Though there is not a wealth of studies looking at the association between DHA and aggression, one recent meta-analysis found a significant negative relationship

between omega-3 polyunsaturated fatty acids and aggressive behavior (Gajos and Beaver 2016).

DHA supplementation appears to have an impact on cognition and behavior. At first glance, the role that DHA plays in the learning and behavior of healthy children seems mixed. Several studies that use pre- and postsupplementation cognitive tests report no significant differences in performance postsupplementation (Kuratko et al. 2013). However, nearly all of these studies also report ceiling effects, where the participant had relatively normal DHA levels and high performance presupplementation.

DHA supplementation appears to be beneficial to those who are most DHA-deficient. For example, although the impact of DHA supplementation in healthy children tends not to lead to significant postsupplementation performance boosts on cognitive tests, there are exceptions. One such exception occurs among children from low socioeconomic status backgrounds (Kuratko et al. 2013). Presumably, these children would be lacking dietary DHA in comparison to higher socioeconomic status children. Attention deficit-hyperactivity disorder is also associated with essential fatty acid deficiency, and DHA/eicosapentaenoic acid supplementation generally has a positive impact on cognitive and behavioral outcomes of children with attention deficit-hyperactivity disorder (Richardson 2006).

Conclusion

DHA is critical in neurodevelopment and likely played a major role in the evolution of the modern human brain. That DHA is a valuable resource may be reflected in the association between DHA and waist-hip ratio, given that waist-hip ratio plays a significant role in female attractiveness and male choice. However, the agricultural era and dietary recommendations to consume more vegetable oil has led to an imbalance in the human diet of the ratio of omega-6 to omega-3 fatty acids favoring the former. This recent underconsumption of DHA is a potential contributor to several diseases common in western

civilizations (i.e., coronary heart disease), behavioral disorders, and deficits in attention and learning.

Does the Chimpanzee Have Theory of Mind?

Adam See
CUNY Graduate Center, New York, NY, USA

Definition

A landmark paper in the philosophy and science of animal minds. David Premack and Guy Woodruff (1978) describe a series of innovative experiments with an adult chimpanzee, Sarah, whom the authors conclude can attribute mental states to her trainers.

Introduction

Premack and Woodruff's "Does the Chimpanzee Have a Theory of Mind?" was published in 1978.

It is amongst the most anthologized papers in the wide variety of disciplines that constitute contemporary animal studies. In the article, a single adult chimpanzee named Sarah is the subject of a series of experiments designed to assess her ability to attribute mental states such as goals, intentions, knowledge, and ignorance to humans. This general ability is indicative of a *theory of mind* or *mindreading* – a capacity long thought to be unique to our species. Premack and Woodruff concluded that Sarah did, in fact, possess a theory of mind. While the author's methods were widely respected, their conclusion was subject to extensive critical scrutiny that continues to this day.

What Is a Theory of Mind?

According to Premack and Woodruff (1978), "An individual has a theory of mind if he imputes mental states to himself and others. A system of inferences of this kind is properly viewed as a theory because such states are not directly observable, and the system can be used to make predictions about the behavior of others." Mindreading hypotheses are commonly contrasted with explanations for animal behavior indicative of *behavior-reading*, a process of social cognition which does not entail mental state attribution. Behavior-reading hypotheses explain the social behavior of an organism strictly in terms of mere associationism or learned behavioral rules acquired through repeated experiences in like-situations. A mindreader, by contrast, goes "beneath the surface to an understanding of the goals, perceptions, knowledge and beliefs that guide action" (Call and Tomasello 2008). To infer another's *mental states* means that one is interpreting that individual's behavior in terms of their underlying intentions, beliefs, doubts, knowledge, and so forth.

Premack and Woodruff's Experiments

In order to determine whether chimpanzees attribute mental states to others, Premack and Woodruff (1978) showed the chimpanzee Sarah a

collection of videos wherein a human actor is attempting to solve a series of problems. These problems ranged from quite simple, such as attempting to find or reach hidden or inaccessible fruit, to relatively complex, such as escaping from a locked cage. The authors paused each 30-s video during the final 5 s, at which time Sarah was shown a multiple photographs, one of which representing the solution to the problem. For instance, in a video where a human actor attempts to attain out-of-reach food, the photographic options consisted of the actor (a) laying on his side and reaching outside the cage with a stick, (b) moving a box, (c) piling concrete blocks into a box, and (d) standing on a box (the correct answer). Essentially, Sarah's task was to select the photograph that completed the sequence of events – a task that Premack and Woodruff suggested was indicative of understanding the goals or intentions of the human actor.

In the more complex scenarios, Sarah was shown videos of an actor attempting to free himself from a cage, shivering next to a faulty heating unit, unable to wash a floor because the hose was not attached to the faucet, and attempting to play a record on a turntable that was not plugged in. Sarah had previously observed humans interact with these objects but had never used them herself. What is more is these complex sequences were never clearly segmented for her. As Premack and Woodruff (1978) claim, they never “made a little ceremony” out of the numerous steps involved in washing the floor or playing a record. In the same manner as the simple cases, the video was paused and Sarah was then shown multiple photographs. This time, the photographs depicted various objects known to her, one of which representing the solution to the problem at hand. For example, in the instance of the faulty heater, the correct photograph was of a lit wick, and in the instance of the caged human, the correct photograph was a key. Sarah scored perfectly on this series. On a more complicated version, more photographs were added, including keys that were intact, twisted, and broken, lit and unlit wicks, and hoses and power cords that

were both damaged and in normal condition. Here, Sarah made only a single mistake, which the authors attribute to the quality of that particular photograph. The purpose of these second tests was to rule out simple physical matching hypotheses.

Finally, “Does the Chimpanzee Have a Theory of Mind?” was the first paper to describe a popular experimental paradigm used to test mindreading capacities: the “knower-guesser protocol.” In this test, in order to retrieve a food reward that is under one of two containers the chimpanzee is asked to discriminate between a trainer who was present during the baiting and a trainer who was not present. The idea is that the chimpanzee should choose the knowledgeable helper over the one who is merely guessing. In a later paper, Premack (1988) conducted this experiment and found that the majority of chimpanzees will, in fact, choose the trainer with knowledge over the guesser.

In sum, Premack and Woodruff (1978) interpreted their findings in the following sense: Sarah not only understood the specific problem represented in each video, she also understood the *goal* or *intention* of the human actors in relation to the problems they were struggling with. As a result of these experiments (as well as others included in the paper but not covered in this entry), Premack and Woodruff concluded that because Sarah had no prior experience with any of these tests, and since she passed the vast majority of the tasks on her first try, hypotheses indicative of behavior-reading or associative learning – while *possible* – are unlikely, and as such the most parsimonious explanation for Sarah's behavior was mindreading.

Critical Commentary: Past and Present

In three independent reviews of this paper at the time of publication, Gil Harman (1978), Daniel Dennett (1978), and Jonathan Bennett (1978) all highlighted what has become arguably the most tenacious and well-known philosophical problem in mindreading debates, commonly referred to today as the “logical problem.” The logical problem boils down to the following: since all we

observe is an animal's behavior, and mental state attribution is an unobservable process, coming up with experiments that can truly distinguish between cases wherein an animal is employing a theory of mind or a behavioral rule when interacting with others is exceedingly difficult – if not impossible.

The most influential proposal to “solve” the logical problem came from Harman's (1978) review, which suggested that if chimpanzees could pass a false-belief test we could be almost certain that they possess a theory of mind. The idea was that if a chimpanzee could correctly predict another's behavior on the basis of that individual's *false* beliefs about the world, rather than what the chimpanzee actually knows to be the case, behavior-reading hypotheses would be ruled out as the chimpanzee would clearly be demonstrating the ability to attribute mental states of belief and knowledge. It took many years for the false-belief test to be tried on chimpanzees. In recent decades, chimpanzees have been evaluated on, and have consistently failed, nonlinguistic variations on the standard false-belief test (see Krachun et al. (2010) for a review).

A critical sea change in experimental paradigms for assessing mindreading in chimpanzees occurred around the turn of the twenty-first century. In an attempt to design experiments in such a way that more closely represented scenarios chimpanzees regularly experience in the wild, experimenters began to garner results highly suggestive of mindreading hypotheses. Arguably the most powerful evidence that chimpanzees possess a theory of mind has come from a series of experiments based on food competition paradigms (e.g., Hare et al. 2001). Rather than testing chimpanzees' abilities to cooperate for food, which is a rarity in their natural habitats, these experiments provided opportunities for chimpanzees competing for the same food to employ deceptive tactics. This was accomplished by placing various occluders between the test subjects, controlling what each chimpanzee could and could not see. Experimenters found that during competitive trials, the actions of subordinate chimpanzees are certainly

affected by what dominant chimpanzees can and cannot see, as well as whether their opponent possesses or lacks prior knowledge of the food source (e.g., Hare et al. 2001).

Conclusion

In the twenty-first century, mindreading remains central to debates over human uniqueness in social cognition. Premack (2007) has claimed that he still defends the view that chimpanzees are capable of attributing intentions to others, though he is highly skeptical of the existing evidence suggesting that chimpanzees can also attribute beliefs or knowledge. Claims of this nature have led many contemporary scholars to describe different *kinds* or *levels* of theory of mind, most commonly in the form of “minimal mindreading” (e.g., Butterfill and Apperly 2013).

On the 30th anniversary of Premack and Woodruff's original paper, Josep Call and Michael Tomasello (2008) published an oft-cited companion-piece summing up much of the relevant experimental research to that date. They note that there is still strong disagreement over whether the logical problem will ever be truly solved, “In a broad construal of the phrase ‘theory of mind’ [...] the answer to Premack and Woodruff's pregnant question of 30 years ago is a definite yes.” By this they mean that despite the fact that chimpanzees consistently fail false-belief tests, there is currently overwhelming evidence that they understand others' goals, intentions, and perceptual states.

While “Does the Chimpanzee Have a Theory of Mind?” did not introduce the question as to whether mindreading is a uniquely human capacity, the extraordinary influence of this paper lies in the ingenuity of its empirical research and the wealth of productive commentary that it engendered. It is fair to say, for instance, that the origins of the false-belief test, the knower-guesser protocol, and the logical problem in animal minds are all directly tied to Premack and Woodruff's landmark article.

Definition

Dominance is the rank of an individual relative to conspecifics, which predicts the outcomes of social interactions and has consequences for access to resources and influence. Perhaps unsurprisingly, dominance rank has consequences for health.

Introduction

Dominance rank has consequences for health, not only due to the access to valuable resources

afforded to high-ranking individuals but also to the stress experienced as a consequence of rank. Depending upon the social system, stress could be highest in the most or least dominant individual, or those in the middle of the hierarchy, and can depend upon the stability of the hierarchy. This may explain the health differentials seen in human populations across socioeconomic status strata.

Dominance and Health

If dominance confers access to resources such as preferential nest sites and nutritious food resources, it makes sense that high-ranking individuals should experience better health than their lower-ranking conspecifics. While this is often the case, there is an additional link between rank and health in the form of the experience of stress. Sapolsky (2005) reviews evidence that high-, low-, and mid-ranks can all be associated with stress and that this is dependent upon the social structure. While some of the highest levels of stress are seen in subordinate members of despotic hierarchies, there are cases (e.g., ring-tailed lemurs and African wild dogs) where the top-ranking individual must aggressively defend their position. Here, physiological measures of stress are very high. Where social ranks are relatively stable, subordinates tend to have physiological indicators of higher stress. When the hierarchy becomes unstable, this pattern may be reversed. He argues that strong and enduring relationships between socioeconomic status and health in humans, such that individuals experiencing socioeconomic deprivation have a greater likelihood of suffering from multiple conditions, including cardiovascular disease, may stem from similar processes.

There may, however, also be health costs to at least some aspects of dominance. In humans, traditional masculinity encompasses traits that likely lead to dominance and is linked to a variety of psychological problems. Positive correlations have been found between masculinity and, for example, stress and suicide attempts (reviewed in Coleman 2015).

Conclusion

Dominance rank predicts health, both as a consequence of differential access to resources but also due to the experience of stress as a result of achieving and maintaining a rank. This may translate into health differences in socioeconomic strata in humans.

Dominance and Territory

Maryam Kamran and Paul A. Moore
 Laboratory for Sensory Ecology, Department of
 Biological Sciences, Bowling Green State
 University, Bowling Green, OH, USA

Synonyms

Control; Influence; Power

Definition

Dominance can be described as a pattern of behavior that results in a consistent outcome with one individual gaining priority to access resources.

Territory can be described as a fixed space or location from which an individual may actively exclude competitors from a specific resource.

Introduction

Territory has long been considered to be a spatial area or location that provides access to resources. These resources can include shelters, access to nutrient-rich food patches, or potential mates. Dominance can be described as the relationship established following inherent displays of aggression between individuals, resulting in the retreat of one. Social dominance is found to be closely related to the acquisition of resources, and territoriality can be described as a form of social dominance (Kaufmann 1983). Assertion of dominance, particularly in acquisition of territory, can translate into control of resources within that territory. This assertion of dominance commonly manifests in dyadic or multiparty contests. The escalation of any given contest is dependent on several intrinsic and extrinsic factors. Intrinsic factors that affect aggression and consequent contest escalation are the size, sex, reproductive status, as well as previous social experience of the individual. Extrinsic factors are the status of the individual within a social hierarchy, the value and availability of a given resource, as well as prior residence. While aggression in an individual has been closely tied to establishing territories, the interaction of both the intrinsic and extrinsic factors will dictate the outcome of the contest to determine which individual would be able to acquire a particular territory and thus the resources associated with the territory.

Examples of Territorial Dominance

Competition for access to resources can result in agonistic interactions between individuals,

whether between conspecifics or between individuals of other species. By asserting social dominance, individuals are able to gain or retain access to resources which can have both direct and indirect fitness consequences. Aggression in crayfish has been extensively studied due to the highly ritualized fighting behavior that exists as well as the development of social dominance hierarchies. Shelters within a particular territory prove to be vital for the survival of individuals by directly reducing the risks associated with predation (Figler et al. 1999). Additionally, the acquisition and retention of shelters housed within a particular territory are often a result of aggressive interactions between crayfish. In many species, males tend to be more aggressive than females; however, in females of *Procambarus clarkii* reproductive status appears to play a role, with “maternal” females having an advantage over others (Figler et al. 1999). Thus, the intrinsic factors can play a role in determining the status of dominance.

There are several factors that play a role in determining the outcome of any given agonistic interaction, with the dominant individual or “winner” gaining access to critical resources such as territory (Moore 2007). The size of the individuals interacting often determines who the “dominant” individual will be, with larger individuals establishing and maintaining dominance. However, another essential determinant is which individual can claim prior residence to a given area. There is evidence of a prior residence effect in which contestants that are residents seem to have an advantage over other individuals. Therefore, the value of a resource as well as prior social experience also influences the outcome of any given agonistic interaction. In studies where food and shelter is present, increased levels of aggression are exhibited by crayfish (Moore 2007). This has been extensively studied in adults but also in juveniles. In contests of male and female juveniles of *P. clarkii*, larger individuals were at an advantage similar to contests between adult crayfish. However, residents in size-matched contests appeared to not only initiate aggressive encounters but also won a greater proportion of the bouts. The prior residence effect in

crayfish combined with the initiation aggression can be attributed to territoriality.

In addition to intraspecies competition for resources such as territory, there are often different species of crayfish competing for the same resources. Several reasons for this interspecies competition can be attributed to the success of one species in displacing another. Primarily, species of crayfish with larger chelae or greater body size tend to win more aggressive interactions and thus are able to acquire access to a particular territory more readily. Another species-specific attribute that lends to resource acquisition through dominance is “intrinsic aggression” (Usio et al. 2001). Interspecies aggression and dominance has been examined particularly in the context of invasive and native species. Research on the invasive North American crayfish *Pacifastacus leniusculus* a larger, fast-growing species when compared to the European native *Austropotamobius torrentium* found that access to the shelter was determined by aggressive encounters, and this dominance was found to be size dependent (Vorburger and Ribi 1999). Additionally, when the use of shelters was examined in each of these species, shelter usage was higher in *A. torrentium* when compared to *P. leniusculus*. This maybe a result of *P. leniusculus* excavating burrows that serve as shelters and thus demonstrating a reduced preference for artificial shelters in a lab setting. In mixed competitions, *P. leniusculus* occupied shelters more frequently. Similarly, comparison of yet another native species (*Procambarus acutus acutus*) to an invasive (*P. clarkii*) demonstrated increased aggressiveness and established dominance. *P. clarkii* demonstrated lower preference for shelters but continued to evict *P. acutus* from shelters. These findings are consistent with the hypotheses that when there is competition for shelter, aggression and social dominance (often dictated by size of the individuals) in invasive species would potentially outcompete the native species. Additionally, the value of a resource such as a shelter is considerably enhanced in an environment where there is a greater threat of predation.

Common crayfish shelters are usually larger rocks or submerged logs; however, some crayfish

species construct their own shelters by burrowing. Studies using the secondary burrowing species, *P.clarkii*, which constructs simple burrows to be used as shelters have found that burrowing behavior is inhibited following aggressive encounters. Construction of burrows is an energetically costly process. Inhibition of this process in the presence of a dominant individual is advantageous when the resident has “lost” recently. Additionally, the inhibition of burrowing behavior can be reversed when the subordinate crayfish is no longer in the presence of the dominant individual. Thus, the formation of a social hierarchy in crayfish tended to affect nonagonistic behaviors as well (Herberholz et al. 2003). As mentioned previously, establishment of dominance by an individual can lead to acquiring greater territory and possibly more resources associated with the territory (Fero and Moore 2008). In crayfish, the establishment of a social dominance hierarchy has a more profound impact than just the acquisition of the immediate resource in question (Martin and Moore 2008). Firstly, as individuals continue to win encounters they are more willing to initiate contests rather than retreat from a contest (Goessmann et al. 2000). Secondly, individuals that are established as dominant appear to initiate and engage in more escalated bouts. Lastly, the “loser” effect appears to persist, with these individuals being more likely to retreat. While crayfish dominance hierarchies maybe shifting, if an individual is established as dominant the “loser” is more likely to lose access to its territory and consequently any resources associated with the territory.

As extensively as crayfish aggression has been examined, the majority of the work has been conducted in artificial laboratory settings. In comparison to fighting within a lab setting, contests in a naturalistic environment tend to be shorter and less intense. Examination of intra-specific aggression in three different habitats, two with varying food resources and one with the presence of shelters, were examined in two species of crayfish (Bergman and Moore 2003). The results were consistent with the hypothesis that in the presence of resources, more inherent displays of aggression would be observed.

Consistent with laboratory studies, fights that occurred in the presence of a shelter were found to be more intense and of a longer duration, signifying the value of the resource. Similarly, of the two different food resources the overall intensities of fights were greater in the areas of the preferred nutrient. However, in comparing the fight intensities within these three habitats, those in the presence of the shelter were most intense. Additionally, when the abundance of a resource decreases in a given area the perceived value associated with that resource increases. Consequently, the competition for the resource increases as do the intensity of aggressive interactions.

Conclusion

Competition for resources often results in agonistic interactions with displays of social dominance resulting in acquisition of a resource. Crayfish tend to exhibit and maintain social dominance hierarchies which in turn translate into control of resources such as a territory with shelter and/or nutrient-rich food patches. Dominant individuals will reinforce their status and thus maintenance of these hierarchies is critical in determining which individual will retain the resources. These hierarchies are dictated by both intrinsic and extrinsic factors with the interactions between these factors playing a significant role in determining which individual can establish dominance and subsequently retain a territory.

Dominance and Testosterone

Definition

Dominance is the rank of an individual relative to conspecifics, which predicts the outcomes of social interactions and has consequences for access to resources and influence. The sex steroid testosterone is linked to aggression and dominance rank and may play a proximate role in dominance behaviors.

Introduction

Testosterone is a steroid hormone secreted primarily from the testes and in smaller amounts from the ovaries. It is responsible for the development of primary and secondary sexual traits in males, and levels surge during male puberty when these traits undergo rapid development. The classic model of testosterone’s relation to dominance was based on early animal experiments showing that administration of exogenous testosterone resulted in increased aggression. While, as discussed in the section *Dominance in Humans*, there are cases in which dominance rank is decided via overt aggression, there are also many instances where this is not the case. It is clear, then, that testosterone alone cannot predict dominance rank in all systems, but there is certainly evidence that it plays a role – albeit a complex one.

Dominance and Testosterone

Under the challenge hypothesis, testosterone levels rise in response to competition for status (Wingfield et al. 1990). Here, the function of elevated testosterone is to promote the aggressive behavior required to win a dominance contest. During a period of instability in the hierarchy, for example, high-ranking rhesus macaques under attack from lower-ranking males had the highest and most variable testosterone levels (Higham et al. 2013). There are also relationships between testosterone and rank in females. In hybrid baboons, for example, females with the highest ranks were also those with the highest testosterone (Beehner et al. 2005). Archer (2006)

concludes that results of human studies are fairly consistent with the challenge hypothesis. There were weak, but significant, positive relationships between testosterone and leadership, toughness, personal power, and aggressive dominance across studies. Both women and men responded to competition with elevated testosterone. Contests, however, as we have seen, do not take a single form, do not occur in isolation, occur in males and females, within and between sexes, and during different seasons, and therefore testosterone is likely to be an imperfect predictor of rank.

There is evidence that relationships between testosterone and dominance are reciprocal, with dominance rank influencing testosterone and testosterone influencing dominance rank. Mazur (2005), for example, reviews evidence from humans that testosterone rises in expectation of a face-to-face dominance challenge such as athletic competition, and post-competition, the testosterone of the winner stays elevated for significantly longer than for the loser. Interestingly, the same patterns are shown in nonphysical contests (e.g., chess matches).

That a number of physical traits correlate both with testosterone and dominance further implicates the hormones' role in predicting dominance rank. Recent work has revealed potential physical cues to dominance in humans, many of which are proposed to develop under the action of testosterone such as facial and vocal masculinity, facial hair, height, and muscularity (see Hill et al. 2013 for a review). Among the most heavily researched of these modalities is facial structure. The degree of masculinity in male faces is positively related both to circulating testosterone and to perceived dominance and actual dominance (reviewed in Valentine et al. 2014). Specific facial dimensions have been proposed to mediate the link between testosterone and perceptions of dominance. Facial width-to-height, for example, has recently received attention due to its relationship with testosterone reactivity to a threat. Results demonstrate that men with greater width-to-height ratios have better financial performance (among chief executives; Wong et al. 2011), are less

likely to die from contact violence (Stirrat et al. 2012), and have higher lifetime reproductive success (Loehr and O'Hara 2013).

Testosterone, however, may also come at a cost, since its effects on behaviors associated with dominance also put the individual at risk of reduced longevity. Global figures demonstrate that men comprise the majority of early and accidental deaths, dangerous and violent crimes, substance abuse, and completed suicides. As Cross et al. (2011) review in their meta-analysis of sex differences in impulsivity, men were significantly more impulsive than women (i.e., less punishment sensitive and more sensation seeking). Since there is some evidence that impulsiveness is linked to testosterone, it is possible that sex differences in testosterone contribute to sex differences in impulsivity and its consequences for longevity. It is important, again, to consider the roles to which men and women are allocated and the expectations and behaviors that come with these. Women, for example, as well as having lower levels of testosterone, are taught to exercise greater self-control in line with a traditional female gender role and men to be more adventurous.

Conclusion

There is evidence to support the challenge hypothesis in humans, with weak relationships between testosterone and measures of dominance such as leadership. The relationship, however, is reciprocal, with testosterone rising in response to a challenge. Testosterone underpins the development of traits which may signal dominance and aggression, such as facial dimensions and vocal masculinity. Finally, testosterone comes with a cost, with links to reduced longevity.

Definition

The acquisition and use of authoritative power over another individual or group reinforced through the signaling or implementation of emotional, physical, or other forms of coercion or compulsion.

Introduction

Humans, like many social species, have a tendency to sort themselves into dominance hierarchies within groups. Functions of these hierarchies include the distribution of authoritative power and determining which individuals are allowed access to resources, alliances, and mates. Dominance hierarchies can include millions of individuals, such as in nation-states and cities, but only two individuals are necessary to create a power differential. For humans, dominance hierarchies can exist in groups such as friend circles or business management and in situations such as interactions with authority figures. There are many behaviors and tactics that humans use to increase their status in these hierarchies, from successfully navigating social situations, to buying their way up with money, to using physical dominance.

Dominance and Force

Physical dominance can be described as a measure of physical behaviors or traits that are used to increase an individual's status within a hierarchy, usually by influencing the behavior of others. A simple example of this is that the trait of being a taller person affords the "right of way" in brief dyadic interactions. When two people approach each other while walking in opposite directions, more often than not, the shorter person will move out of the way to let the taller person pass by (Stulp et al. 2015). Although the physical size of an individual is a salient indicator of their ability to inflict harm on others, it is not necessarily an indicator of the likelihood that they will behave in a dominant way. However, when judging an individual's level of physical strength and level of dominance based on their facial appearance, both judgments correlate highly and may be considered as functionally the same (Toscano et al. 2016). Humans use cues like these as a means of determining the likelihood of the use of force when navigating hierarchies.

Humans use more explicit signals as well. Gestures like facial expressions, vocal cues, and eye gaze are sufficient behaviors to affect changes in power structures. For example, behaviors such as tilting the head down in pitch while maintaining eye contact are seen as an indication of anger (Toscano et al. 2018) and thus can imply the increased probability of an impending dominance challenge by physical force. These signals, and the benefit that the ability to interpret them provides, are likely evolutionary adaptations. This is due to the risks involved when using physical force. Dominance signals allow for the mutual avoidance of engaging in actual physical violence while maintaining status quo. Although these signals likely developed in the more combative ancestral past of humans (Sell et al. 2009), the threat or use of force still has utility in modern times.

As mentioned above, nonverbal cues can be used to signal the threat of the imminent use of force in an attempt to dominate others. However, nonverbal behaviors can also be used as behavioral indicators for targeting potentially

submissive individuals to dominate. In film-based stimuli, those who were rated as being vulnerable to victimization moved in ways that were systematically different from those who were not rated as vulnerable. This finding has been supported in a variety of ways including the use of point-light kinematics and videotaped walking styles/gait (Book et al. 2013). For the most part, the sending and receiving of these social signals serve to establish and maintain social dominance hierarchies. However, sometimes social interactions result in the threat or use of force.

Force is a broad concept, and the variation in types of threat or force used in obtaining or reinforcing dominance reflects this. The armed services and police forces of nation-states use an escalation of force model and train their members vigorously in its use. This model is used to assess threat and assert dominance in order to control social situations, often involving large groups. In the case of state versus state interactions, force can range from direct or indirect communication between leaders to full military engagement. In the case of policing the general public, officers' use of force can range from the mere presence of a soldier or police officer to the use of deadly force (Bagwell 2008). A similarly broad range of behaviors can be used to threaten or instigate physical force in individual interactions. These include verbal and nonverbal cues, coercion/manipulation, threats of violence, reputational coercion through violence to others, and the direct use of violence.

Verbal threats can be used to ward off rivals and establish dominance in order to cope with the threat of others. Verbal behaviors can also be used to manipulate and coerce and may include verbal pressure, emotional and physical threats, and deception (Finkelstein 2014). Manipulation and coercion use nonverbal, verbal, and physical cues to instigate the giving of some benefit to a conspecific without the intention or expectation of reciprocation (Clutton-Brock 2009). Manipulation and coercion are often used in close interpersonal relationships as a method of establishing and maintaining dominance. Buss (1992) found that the use of manipulative and coercive tactics

is more common in closer interpersonal relationships (i.e., romantic partners are manipulated/coerced more than friends). Further, the use of manipulative/coercive behaviors is related to high levels of the personality traits boldness and disagreeableness. These personality traits and the use of manipulation/coercion are also related to psychopathic behaviors, a socially exploitative phenotype that utilizes a mixed strategy involving both cheating, intimidation, and violence to increase access mating and resources (Book and Quinsey 2004). A key sex difference in psychopathic behaviors and the use of threat or force in order to establish dominance is that females tend to rely more on verbal aggression, manipulation, and coercion, whereas males more regularly threaten and/or instigate violence (Carabellese et al. 2019).

Interpersonal and intergroup physical violence can be used to establish dominance and facilitate social exploitation, this occurs because to the receiver(s) of violence the loss of reputation or resource is less detrimental to their fitness than the cost of incurred violence (Buss and Duntley 2008). For the perpetrator(s) of violence, it serves to not only increase their access to resources and mating opportunities but confer long-lasting benefits through reputation by increasing social dominance and in turn social capital. Dominance through the use or threat of violence begins during childhood and adolescence, with schoolyard bullying commonly occurring. Mynard and Joseph (1997) found that in 8- to 13-year-old schoolchildren, bullies had lower levels of self-esteem and higher levels of neuroticism than controls but targeted victims who had high levels of introversion and lower levels of self-esteem than themselves. In this way bullies could use violence to increase their reputations by establishing dominance over others.

Secondary victimization occurs as the result of damage to an individual or group's reputation following interpersonal violence. The physical dominance of the victor(s) is established and serves as a signal to others. As a result the reputation of physical dominance of the perpetrator of

violence increases, while the reputation of the victim is harmed (Duntley and Shackelford 2012). One reason that reputational coercion is so effective at establishing and maintaining dominance in a group is that human memory is biased toward the recall of distressing events. Lalande and Bonanno (2011) had participants' self-report events over a period of 4 years by responding weekly to a survey assessing whether events from a list of 50 options had occurred. Events fit four categories; potentially distressing events, academic or financial stressors, interpersonal stressors, and lifestyle changes. At the end of the 4-year period, participants estimated how many times each of the 50 events had occurred. Participants generally underestimated the frequency of each event but gave more accurate responses for potentially traumatic events. Further, distress at time of recall was related to the number of events recalled only for potentially distressing events. One of the most accurately remembered events was the experience of robbery or mugging.

Conclusion

Dominance plays an important role in human social hierarchies and social interactions at both a group and an individual level. Dominance can be established in multiple ways including social manipulations, control, and distribution of resources and physical superiority. The possible use of force as a way of establishing or reinforcing of dominance is signaled between individuals and groups using methods that range from subtle signals (facial expressions, vocal tones, etc.) to overt signals (direct or indirect violence). Force can also be used in forms ranging from manipulation and coercion to primary and secondary physical violence.

Definition

Dominance hierarchy is a social structure of a society or a family. Within this structure some individuals are more dominant than others and as such have access to greater (or better) resources (i.e., food, mates, etc.). Dominance hierarchy enables to decrease number of conflicts between individuals because some give way to the others and let them have resources without fighting. This behavior is mostly based on their experience from previous interactions. Moreover, the higher ranking ones restrict the lower ranking individuals.

Introduction

The term *dominance hierarchy* (McFarland 1981) refers to hierarchical ranking of individuals in a society (in a group, a family, a clan, or a pack). Terms such as *social hierarchy*, *social dominance hierarchy*, and *peck order* (McFarland 1981; Manning and Dawkins 2009; Veselovsky 2005) have similar meaning. The concept of dominance hierarchy is widely used and has been explored in depth in animals, including primates. In humans, the same feature is expressed by socioeconomic status, social status, or power.

The dominance hierarchical rank influences the probability of an individual's survival. The likelihood of getting food, space to rest or hide from predators, the chance to mate, or the quality of a sexual partner – all these facts depend on the hierarchical rank. An individual's rank within the dominance hierarchy strongly influences the life of both humans and animals.

How it Works

Dominance hierarchy refers to the way the society or the family is organized (Veselovsky 2005). The relationships in a dominance hierarchy are called *dominance-subordination relationships*, or *dominance-submission relationships*. The higher ranking individual is considered a *dominant* individual, while the lower ranking individual is called *submissive* or *subordinate* (Jozifkova

2014). Individuals are frequently ranked and named according to the Greek alphabet. The most dominant individual is titled the alpha (α); the second highest ranking individual is the beta (β), followed by the gamma (γ); and the most submissive one, subordinate to them all, is the omega (ω) (Veselovsky 2005).

The rank ordering decreases the number of conflicts between individuals (Manning and Dawkins 2009) and increases the cohesion between members of a group (Veselovsky 2005). When individuals compete for the same resources, conflicts arise. Even genetically related individuals are not spared from mutual conflicts in the competition for the resources. However, the conflicts are costly (the individual may lose energy that otherwise could be used for survival and/or reproduction) and may result in injuries or deaths. Based on their previous experience, the individuals living together in the group remember those who beat them in the conflict or recognize features of those who are likely to defeat them. The individual may identify such rivals by cues (e.g., body size) and/or badges of status (e.g., the black bibs of male house sparrows). Thus, the individuals are able to predict the outcome of the conflict. So the lower ranking individuals retreat to the stronger members (Manning and Dawkins 2009). Dominance hierarchy means that social *ranks* are established in the group, so that some individuals yield to others and allow them to have scarce resources without fighting (Alcock 2013). Mostly, lower ranking individuals let the higher ranking individuals feed first and leave them safe places for rest and sexual partners (Manning and Dawkins 2009). Lower ranking individuals are restricted by higher ranking individuals. The dominance rank is maintained by higher ranking individuals, who threaten the lower ranking individuals in a specific way, i.e., direct gaze, upright posture, showing teeth or “weapons,” etc. (Manning and Dawkins 2009; Veselovsky 2005).

The lower ranking individuals try to avoid the conflict with the higher ranking ones (McFarland 1981). They display submissive behavior to signalize their lower rank (McFarland 1981). A *submissive posture* (McFarland 1981) stops or

slows down aggression between the same species of individuals (Veselovsky 2005). *Appeasement behavior* (McFarland 1981) helps to manage the situation in a way it unblocks another kind of behavior (e.g., a shift to parental or sexual behavior).

The dominance hierarchical rank of the individual in a society depends primarily on his ability to fight (and/or to be supported by those who are able to fight). Dominance hierarchy is a strategy how to survive in a given environment. The form of social hierarchies differs depending on the natural conditions (Manning and Dawkins 2009). The dominance hierarchy is defined by both the mating systems (polygyny versus polyandry versus monogamy) and social organization.

In detail, the environment (namely, the distribution of the resources) impacts the size of a group and thus influences both the social organization and the mating system which can be considered behavioral adaptations. A species survives under given environmental conditions because of behavioral adaptations. Species of weaver birds which live either in forests or savannahs are the example of such an adaptation. The forest species live solitarily because the resources of food are dispersed. The savannah species live in bigger groups because the resources of food are clumped together. While the forest species are monogamous, the majority of the savannah weaver birds is polygynous (Davies et al. 2012).

The males tend to have bigger body size than females and ranked higher than females in species with polygyny mating system, while the females may be bigger and may rank higher than males in polyandry mating systems. But there are some exceptions: in ring-tailed lemur, all adult females rank higher than males despite that the ring-tailed lemurs have polygynous mating system.

The higher ranking animals guarantee the stability within a group; they protect the group (the group primarily includes their sexual partners and offspring, and by their protection the higher ranking individual increases its fitness) and secure resources which are important for the group. Frequently they make decisions. Their experience often brings benefits to the group (Veselovsky 2005).

Living in the group allows the lower ranking ones to survive, participate in reproduction, or increase their fitness indirectly by supporting their relatives (Jozifkova 2014).

Different Dominance Hierarchy Structures

Peck order in poultry is an example of *linear hierarchy*. The higher ranking hen pecks the lower ranking individuals (McFarland 1981). The most dominant animal (alpha) is not pecked by any other animal. The second higher ranking (beta) is pecked only by the alpha. The third animal is pecked only by the alpha and beta, but it can peck everybody else except the alpha and beta. The lowest ranking animal is pecked by all other animals (Manning and Dawkins 2009).

Individuals of large groups may not know each other in person. In these groups, an *incomplete hierarchy* occurs frequently. The higher ranking animals are easy to spot, while the hierarchy between members of the base is unclear (Franck 1996).

The hierarchical structure is sometimes more complex. An alpha rank is higher than beta, and beta dominates the gamma, but the alpha may not dominate the gamma (Manning and Dawkins 2009). This is example of *angular* (Franck 1996) or *circular hierarchy*.

The society can be governed by more than one individual. Frequently, more experienced individuals make a coalition so that they can control the society accordingly (Veselovsky 2005; Franck 1996).

A society has either one dominance hierarchy that includes all members of the society or separate hierarchies for males and females (Veselovsky 2005). The hierarchy separates when males and females compete for different resources. In free-living rabbits, the males compete for the females, while the females compete for a place to make a burrow, and therefore there are *separate hierarchies*. However, the sibling group of a domesticated rabbit which lives in the small space under artificial conditions forms a single linear hierarchical structure, including both male and female (Vervaecke et al. 2010).

The hierarchies differ in rigidity of rules which control mutual behavior between members of a group and between groups. Animal species can be classified as tolerant (small hierarchical disparity) and despotic (big disparity). The terms *dominance gradient* (Jacobs et al. 2011) and *steepness of the hierarchy* (Vervaecke et al. 2010) describe the gap between the higher and the lower ranking individual.

The “vote” of the higher ranking animal is of higher value when the group makes a decision (Jozifkova 2014).

A leader (the individual in the head of the group on the move) or an initiator (an animal which starts with an activity first) might not be the higher ranking animal (Ihl and Bowyer 2011), i.e., it could be an elderly or middle-aged animal who knows the landscape. Lead animals may differ in different situations (Jacobs et al. 2011).

How the Dominance Hierarchical Rank Is Determined

The dominance hierarchical rank is determined by factors which help to win the interaction (usually fight or ritualized fight). The important factors, either individually or combined, involved body size, condition (health, rutting/pregnancy, age), gender, experiences, hierarchical rank of parents (some species inherit a rank from the mother), family or clan, partnership (having a partner), rank of partner, ability to change behavior of the others (manipulation and cooperation), and personality, including aggression and inherited tendency to dominate or subordinate (character dominance) (Veselovsky 2005; Jozifkova 2014).

An individual reaches the higher rank by winning either the real fight or a ritualized fight (McFarland 1981), or via positive interactions (Manning and Dawkins 2009). Grooming is an example of the positive interaction (Manning and Dawkins 2009).

Individuals clash in the ritualized fights under inborn rules which are inherited from generation to generation. These animals usually have special physical structures (such as antlers)

which decrease the probability of an injury (Veselovsky 2005).

Notably, the interactions between individuals who are closely matched in their levels of a specific trait/characteristic (e.g., battle between the same strength in deer, the conflict between women of the same attractiveness, etc.) are most severe, whereas the individuals who differ markedly in the specific characteristic give up the fight quickly.

Aggressive behavior or this tendency can help to increase the rank of an individual, especially when the hierarchy is still establishing. The aggressiveness helps one to reach a higher position if the rival is unsure and backs off.

How the Hierarchical Rank Influences the Life of an Individual

Dominance hierarchical rank directs the life of an individual. The rank predicts the probability of survival and reproduction; in terms of evolutionary biology, it impacts inclusive fitness, i.e., how an individual participates in reproduction or supports its relatives who reproduce (Jozifkova 2014).

The higher ranking individuals have higher probability of survival because dominant individuals get priority access to resources, such as fine food, safe places to rest, space distant from predators, places which are free of parasites, and other suitable environmental conditions. The higher ranking individuals have better chances to mate. Moreover, they can mate with higher Quality partners. This fact, together with better access to resources, causes the offspring of the higher ranking individuals to be stronger, more numerous, and survive better. Thus the higher ranking individuals achieve higher fitness. On the other hand, there are costs. These individuals have to invest a significant amount of energy to reach and defend their higher rank.

When unable to compete with higher ranking males, a lower ranking male can use alternative Reproductive tactics to steal the opportunity for reproduction from higher ranking ones (Alcock 2013).

The lower ranking individuals lose in the interaction with the higher ranking ones, which results in hormonal changes, such as an increase of the cortisol level. These changes have a negative impact on their health. The higher the number of high ranking individuals, the more stressed the lower ranking individuals are (Jozifkova 2014).

The ways and options how the individual can behave in a society or a family are influenced or even determined by his or her hierarchical rank. The hierarchical rank also shapes communication between individuals, such as the quantity and quality of information transferred between humans. For example, the submissive individual tends to agree and suppress his/her opinion and gives the dominant individual more information than is necessary, while the dominant individual controls the topic and the length of the communication, asks questions, and hides information. Rank plays a crucial role during courtship and partner choice. Women do prefer higher ranking men. While the higher rank increases attractiveness of men, physical attractiveness of women increases their rank. On the other hand, a portion of women is sexually aroused by lower ranking men.

Partner violence, bullying, and mobbing may be seen as an extreme manifestation of dominance hierarchy in which the perpetrator repeatedly slashes down the hierarchical rank of the victim (Jozifkova 2014).

Conclusion

A society or a family is hierarchically organized on the basis of probability of winning or losing an interaction between members of the group. It is a way how group members can avoid repeated fighting. Therefore, an individual usually behaves in agreement with his or her hierarchical rank. Higher ranking (dominant) individuals restrict the lower ranking (submissive, subordinate) ones and have priority access to resources, spaces, and sexual partners. Thus, the higher ranking individuals have increased fitness. A lower ranking individual has a chance to survive by staying in the society. They can support their relatives who

reproduce, but circumstances may even bring them opportunity to participate in mating directly. The rank of an individual changes according to his or her ability to win interactions. Dominance hierarchy is an adaptation of a society to local ecological conditions. Therefore, the structure of hierarchies differs under different conditions. Hierarchy can be linear or circular, can be markedly distinct or indistinct, may include both genders or may be gender-divided, may be led by the highest ranking individual or a dominating coalition, and may be tolerant or despotic with a severe slope. The hierarchical rank determines the behavior of an individual. These facts should be borne in our minds when observing or analyzing human behavior.

Synonyms

Status; Social status; Prestige

Definition

Dominance is the rank of an individual relative to conspecifics, which predicts the outcomes of social interactions and has consequences for access to resources and influence.

Introduction

An individual's rank relative to its conspecifics is a predictor of behavior, health, and reproductive output across the animal kingdom. When talking about animal societies, this is typically described in terms of dominance rank, which is determined by the outcome of contests for access to resources such as food or mates. In humans, the picture is far more complex and dominance is the product not only of direct physical contests between individuals ("physical dominance") but of prestige,

group membership (e.g., based on gender or ethnicity), and situation within large-scale "formal hierarchies" such as socioeconomic status.

Dominance in Humans

Wherever social groups exist, a dominance hierarchy will inevitably emerge, with unequal access to resources such as food and mating opportunities. The relative rank of an individual amongst its conspecifics can depend upon, for example, its size and strength, age, experience, aggression, matriline (i.e., the status of its own mother), or the quality of its coalitionary relationships. Hierarchies differ in their fluidity and linearity, the top spot may be occupied by a single individual or shared, and the hierarchy may be established and regularly enforced in the case of permanent groups or only become relevant occasionally, such as during the breeding season.

Taking primates as a case study (while acknowledging that the patterns reported are seen in the animal kingdom more widely), there are examples of societies in which reproduction and access to prime territories and food resources is dominated by a single individual. This is the case in, for example, gorillas, ring-tailed lemurs, and blue monkeys, where there is a single top-ranking individual to whom the rest of the group defers. In these despotic hierarchies, there are usually few status differences amongst the rest of the group. In contrast, in an egalitarian hierarchy, dominance relationships are "transitive": each individual can beat all those ranked below her but none of those ranked above her (e.g., chimpanzees, lion-tailed macaques, and squirrel monkeys).

Dominance rank is usually estimated via observation of associated behaviors, such as who is approached or avoided by whom, gestures, and access to mates, food, or nest sites. Most commonly, rank is assessed by observing "contests" between all dyads in a group and recording the outcome (who is successful and who retreats). From these data, a matrix can be developed which allows the researcher to rank individuals on the basis of outcomes in contests across all

dyads. These dyadic interactions, however, do not occur in isolation and there is a growing body of work which shows that the wider social context influences behavior and outcomes in these interactions. Laporte and Zuberbühler (2010), for example, report that the “pant-grunt” signal of chimpanzees, which is used as a greeting signal to higher-ranking individuals, was expressed more often by females to males if the alpha male and/or female were absent and was further inhibited the greater the size of the audience of bystanders.

Dominance in humans is much more complex than the primate cases described above and is the product not only of direct physical contests between individuals (‘physical dominance’) but of variables such as prestige, group membership (e.g., based on gender or ethnicity), and situation within large-scale “formal hierarchies” such as socioeconomic status. Furthermore, humans do not – usually at least – exhibit such obvious dominance behaviors and displays as the other primates. There are, however, markers to status with, for example, high-status individuals dominating conversation by talking longer, louder, and interrupting more often (Dunbar and Burgoon 2005). Humans are also reasonably good at telling us who, in their group, is a leader and who is a follower, thus providing an estimate of “influence.” Furthermore, we assign status on the basis of a myriad of physical (e.g., beauty, strength, ethnicity, gender) and behavioral (e.g., humor, leadership, intelligence, personality, social class) traits, regardless of whether there is validity to the assumption that some groups deserve to be positioned in higher ranks than others.

Physical Dominance

Physical dominance can play out in the context of face-to-face interactions and can take the form of both overt physical contest (as in the case of fights) but can also take more subtle forms such as verbal and nonverbal signals (e.g., body posture and lean; Dunbar and Burgoon 2005). Furthermore, physical dominance can be expressed via large scale, formal contests such as warfare. As Mazur (2005) argues, while these play out on national- and international-scales, often with

considerable loss of life, and usually over competition for power and resources, there is often a personal motivation underlying these extravagant dominance contests.

Prestige

As is the case in the primate examples discussed above, status can be ascribed on the basis of access to resources, but in addition to this, the extent to which an individual is popular and exerts influence (or their “prestige”) is closely linked to status in humans. Prestige is earned by the expression of skill, rather than the ability to win physical contests or otherwise coerce others to one's will, and is associated with prosociality and leadership across traditional societies (see Henrich et al. 2015 for a review). Cheng et al. (2013) demonstrate that coercion and prestige are also distinct pathways to status in laboratory group tasks involving undergraduate Canadian students. Here, participants were able to attain status either via coercion via force and intimidation or via sharing of knowledge and expertise (prestige). Interestingly, popularity was not linked to status, with those following the route of “prestige” securing significantly greater popularity.

Official Hierarchies

Human dominance in face-to-face dyads and groups is situated within a structure of “official hierarchies” such as governments and socioeconomic strata (see Mazur 2005 for a review). These broad, formal, ranks organize access to resources, power, and influence, with a small number of “leaders” atop a series of levels of decreasing status and increasing numbers. Individuals may or may not know others in the levels above or below them, so here the formal status conferred by level in the official hierarchy interacts with the informal status derived from face-to-face interactions with those within one's immediate group. Occupation of positions in these official hierarchies has profound effects on our psychology. An extreme example of this comes from Zimbardo's classic “Stanford Prison Experiment,” in which groups of students were arbitrarily allocated to the role of “guard” or “prisoner” with consequent manifestations of extreme dominance behavior by

the guards and deference by the prisoners (but see Haslam and Reicher (2012) for evidence that these effects can be mediated by, for example, permeability between roles).

Sex, Gender, and Status

One way in which we organize ourselves, and which has profound effects both on attributions of status and on the ways in which status is negotiated, is by sex. Men and women look and act differently from one another in a number of ways. Men's larger size and greater upper body strength, and women's greater investment in gestation and early infant care, are argued to have evolved under conditions of mild polygyny with greater competition amongst males for mates than amongst females (Archer 2009; Puts 2010). These biological sex differences likely predisposed men and women to efficient performance of different tasks which, over time, were attributed with different "status." While men had a physical composition better suited, perhaps, to hunting, women's biology provided the conditions for heavier investment in early offspring care. This not only set the scene for different selection pressures for men and women (who, to an extent, occupied separate ecologies as a result of their biology), but may also have resulted in the adoption of tasks which not only furthered the divergence in male- and female-ecological niches, but also conferred different levels of status to the two groups. The meat won through hunting is a valuable nutritional resource which can be traded and, therefore, confer status. In their biosocial model, Wood and Eagly (2012) argue that biological differences between men and women predisposed them to different social roles within communities which, in turn, influenced many of the traits and behaviors which we consider to be "male/masculine" and "female/feminine" today. For example, the greater assertiveness, aggression, and agency of the male gender role is certainly consistent with the requirements of competing for valuable physical resources. The nurturing and social traits of the female gender role are, in contrast, perhaps the result of a history in investment in caregiving. These pathways that flow from biological sex differences to the allocation of distinct tasks and

responsibilities to men and women, to the behavioral and psychological traits required to fulfill these gendered social roles, likely had multiple consequences for the ways in which men and women establish dominance amongst same-sex conspecifics and also for the dynamics of between-sex interactions.

Male dominance is reported to be expressed via physical displays and contests more often than is the case for women and this. Men are more likely than women to respond to threats with aggression, particularly when there is an audience of other men (i.e., future potential competitors) and to participate in inter-group conflict (see Buss 2015 for a review). In addition, men score more highly on measures of "social dominance orientation," which assesses preference for unequal status across groups. This is, perhaps, not entirely unsurprising given the likely stronger intrasexual selection on men to compete for mates due to an asymmetry in investment in gametes and, at minimum levels, in offspring (Archer 2009). Male dominance, however, is not as straightforward as success in physical contests. von Rueden et al. (2008), for example, investigated male status in a population of Amazonian Tsimane hunter-gatherers. The authors argue that this community provides a meaningful case study for conditions under which social life likely evolved over much of our evolutionary past. They report that physical size and social support predicted the outcome of dyadic physical contests amongst men: being larger and with more coalitionary support resulted in greater physical dominance. Social support also predicted "influence" and "respect," as did hunting ability. The authors argue that male status is multidimensional and is dependent not only upon physical individual differences, such as a man's size and age, and also upon the strength of one's coalitionary support. Furthermore, status differentials in this population are related to proxies of reproductive success, with high-status men having more extra-marital relationships than those of lower status (von Rueden et al. 2010).

There is evidence to suggest that women use indirect aggression to a greater degree and direct physical aggression less, than do men in order to influence their own status and that of others.

Perhaps the most classic example of this is accusations of witchcraft, in which an individual's reputation is degraded by untestable accusations, with women more commonly accused (see Hess and Hagan (2006) for a review). This may be due to the high costs to women's fitness of direct physical aggression (due to investment in needy offspring), and therefore more indirect forms of aggression may have evolved (see Stockley and Campbell 2013, for a review). Much as male status via acquisition of resources necessary to invest in offspring may be desirable to the opposite sex, perhaps female status is bound up in the traits which make her desirable to men, such as physical attractiveness and chastity. Vaillancourt (2013) suggests that women use two broad strategies to appear attractive to mates: self-promotion (displaying physical attractiveness) and rival derogation (disparaging appearance and fidelity). Hess and Hagan (2006), for example, report that women in a laboratory task were more likely to express desires to retaliate to a threat by attacking reputation than were men.

As argued, however, the behavior of men and women cannot be interpreted in light only of their biology. Biology exists within, and interacts with, a social context. Archer (2006), for example, reports that sex differences in physical aggression against a partner is correlated societal gender equality, such that the size of the sex difference was reduced under conditions of greater equality.

Dominance and Reproductive Success

Across species, high-ranking individuals obtain more food and have greater reproductive success. In primates, for example, high-ranking males tend to have more offspring than do those of lower ranks. This, however, is not a straightforward linear relationship and is most likely influenced by factors such as the numbers of male competitors and receptive females, male coalitions, female choice, female reproductive synchrony, and alternative male mating strategies (see Clutton-Brock and Huchard. (2013) for a review). The relationship between rank and reproductive success is equally variable in female primates. In order to interpret variation in the magnitude of the

relationship between rank and fitness, Clutton-Brock and colleagues call into question the assumption that that status and fitness should be more closely linked in males than females, due to the asymmetry in minimal investment in reproduction by mammalian males and females. The interpretation and application of this classic model has come to treat the proposed dichotomy of competitors (typically males) and choosers (typically females) almost literally, with a greater research focus on competition for resources and status amongst males than females. In their review of a growing body of evidence that females can compete for resources and status to the same extent, or more vigorously, than males, Clutton-Brock and Huchard (2013) show that there are relationships between the degree of reproductive competition and physical traits associated with attracting mates and with intrasexual competition in both sexes. They argue that sex differences in effects of status on fitness (i.e., that status is often more closely linked to fitness in males) may have been over-estimated due to differences in the breeding lifespans of males and females and that without direct comparisons of relationships between rank and fitness of males and females, it is not possible to conclude that selection pressures on traits associated with status vary between the sexes.

As a case study of the above, status and reproductive success are correlated in both men and women, albeit the strength and direction varies. Various measures of status are positively related to number of men's surviving offspring in traditional societies (see Hopcroft 2006 for a review); high income men have more biological children in the contemporary USA whereas years of education is inversely related to reproductive success in both men and women (Hopcroft 2006). Nettle and Pollett (2008) report positive selection for male wealth due to higher childlessness amongst low-income men across eight societies but a negative relationship between income and reproductive success in women. Fieder and Huber also show that income is associated with fewer children for women and more for men (2007). Here it seems likely that interactions between the biology and social-role occupation of men and women are at play. It is interesting to imagine, for example,

whether in a hypothetical society in which there was full gender equality in the opportunity to balance education, employment, and childcare, inverse relationships between wealth and reproductive success would exist to the same extent for women or between education and reproductive success for men and women.

Conclusion

There are sex differences in the expression of aggression across species, and of direct and indirect aggression in humans, stemming from divergent intrasexual selection pressures. This, however, is qualified by evidence that sex differences may not be as large as previously assumed and vary with context, such as societal level of gender equality in humans. Dominance in humans is perhaps best viewed as the status that results from the relative positioning of an individual within their local groups and communities (negotiated via either prestige or coercion) which, in turn, is situated within – and interact with – the context of large, formal, status hierarchies. While there are many remaining unknowns, what is clear is that an individuals' rank has profound implications for his or her life history.

Dominance Theory (Cummins)

Denise D. Cummins
 Department of Psychology/Department of
 Philosophy, University of Illinois, Champaign,
 IL, USA

Definition

A theory proposed by Denise D. Cummins that interprets specific social cognitive functions as adaptations to the exigencies of living in a dominance (or status) hierarchy.

Introduction

Eight decades of empirical investigation have unequivocally demonstrated that human reasoning performance varies as a function of problem content. Problems with identical formal properties but different subjective contents often produce vastly different levels of performance, a phenomenon referred to as *content effects*. The most

robust performance differences are observed when people are asked to reason about rules that describe constraints on behavior, such as permissions, obligations, prohibitions, or warnings. When asked to test the truth of such rules, people invariably and wrongly adopt a confirmation bias strategy, choosing to investigate cases that could prove the rule true rather than those that could prove the rule false. The latter strategy is the only one that can provide incontrovertible proof concerning the truth status of the rule (Popper 1959). In contrast, when asked to test compliance with the rule, people invariably and correctly choose to investigate cases of possible non-compliance, that is, to seek to discover whether someone is doing something that is not permitted or is failing to do something they are obligated to do. Permissions, obligations, and prohibitions are called deontic concepts, and reasoning about what one may, must, or must not do in a given set of circumstances is called *deontic reasoning* (Hilpinen 1981). The superior performance elicited by deontic content is called the *deontic advantage* in human reasoning.

Several explanations have been offered for the deontic advantage. One of the most influential is social contract theory, which was proposed by psychologist Leda Cosmides (1989). According to the theory, social contracts are cases of reciprocal cooperation for mutual benefit. When a reasoning problem is interpreted as a social contract, a genetic “look for cheaters” algorithm is spontaneously triggered that causes people to investigate individuals who have accepted benefits (to ensure they have paid the required cost) and individuals who have not paid the cost (to ensure they have not accepted the restricted benefit). The difficulty is that problem contents that elicit a violation detection strategy do not always define opportunities for two individuals to participate in mutually beneficial cooperative transactions. Instead, they typically describe deontic rules that are more appropriately described as *social norms*, constraints created by authorities that dictate what is permitted and obligated when specific conditions apply. For example, the cassava root scenarios used by Cosmides (1989) describe a rule created by village elders or a chief named “Big Kiku” that

restricts the eating of cassava root to members of a particular tribe. Scenarios like these do not describe a reciprocal exchange between two individuals. They instead describe a social norm created and enforced by village authorities. “Cheating” does not take the form of failing to reciprocate a benefit. Instead, it takes the form of failing to comply with an obligatory rule that is imposed by authorities on subordinates. Stanovich and West (1998, Experiment 1) found that adult performance plummeted from approximately 80% to 30% when reference to authority was removed from “social thematic” problem descriptions. Compliance with norms – not reciprocation – is expected and required. Moreover, social norms may or may not be mutually beneficial. Indeed, social norms may have as their goal the exploitation or subjugation of one group of individuals by another, privileged group.

Dominance Theory

To address this discrepancy, psychologist Denise Cummins proposed *dominance theory* (Cummins 1996a, b, c, 1998, 1999, 2000, 2001, 2002, 2004, 2005, 2013a, b, 2016a, b; Cummins and Cummins 1999, 2003). The core tenet of the theory is that social cognition (including the deontic advantage) was shaped by the continual need to survive within dominance (or status) hierarchies, the social organization that is ubiquitous in the societies of humans and nonhuman animals throughout evolutionary time. High-status individuals are essentially authorities in this type of social organization, monitoring and controlling the behavior of subordinates in order to maintain priority of access to competitive resources (such as food and mating opportunities). Dominance theory posits five main cognitive functions that were shaped by the exigencies of living within status hierarchies: rank discrimination, acquiring social norms, monitoring compliance with social norms, monitoring reciprocity, and flouting social norms through deception.

Evolutionary theory is based on the assumption that there is a causal relationship between the adaptive problems a species repeatedly

encounters during its evolution and the design of its phenotypic structures, including cognitive and behavioral traits. Solving problems of social competition and cooperation has direct impact on survival rates and reproductive success. The ubiquitous social structure that evolved from this pressure is the dominance (or status) hierarchy, a social organization in which some individuals have regular priority of access to resources and fertile mates in competitive situations. These individuals are referred to as high status (or high ranking). Individuals who have lower priority of access are called subordinate or low status.

From a cognitive standpoint, status hierarchies can be interpreted and analyzed as systems of implicit social norms that impose constraints on what is permitted, obligated, or prohibited based on one’s status within the group. Surviving within a dominance hierarchy depends crucially on the capacity to learn these constraints, the capacity to recognize violations of these constraints, and the capacity to use deceptive strategies to flout these constraints in order to garner a larger share of resources. Failure to do so carries a high risk of eliciting agonistic encounters or ostracism. According to the theory, the deontic concepts of permission, obligation, and prohibition are primitives (innate concepts) in the cognitive architecture of social animals that were selected for because they were crucial for survival within status hierarchies. It is these primitive concepts that confer the deontic advantage in reasoning performance.

Support for the theory comes from six sources: comparative psychology (particularly primatology), developmental psychology, anthropology, behavioral economics, neuroscience, and cognitive psychology.

Primatology. *Homo sapiens* is a primate species whose ancestors diverged within the primate line a scant five million years ago. Because evolution builds upon existing structures, studying nonhuman primates can provide insight into the characteristics of human reasoning that reach deep into our evolutionary past, prior to the splitting of hominids within the primate line. The most striking of these characteristics is that, like human reasoning, the reasoning of nonhuman primates

is subject to content effects, and social content provides the most robust effects. For example, nonhuman primates readily make rank discriminations among individuals in their social groups, even when all possible dyadic interactions are not directly witnessed (Cheney and Seyfarth 1990, pp. 91–96): They readily infer that A is dominant to C if they witness interactions in which A is dominant to B and B is dominant to C. In contrast, they can perform transitive inference on object-oriented tasks only after considerable drilling with paired stimuli (Gillan 1981).

Primate status hierarchies are replete with “implicit social norms” that dictate who is allowed to groom, sit next to, play with, share food with, and mate with whom. In order to avoid punishment (or ostracism, which can mean death due to predation or starvation), individuals must learn what is *permitted*, *forbidden*, and *obligated given their place in the hierarchy*. High-ranking individuals monitor the behavior of subordinates in order to protect their privileged access to resources. They also frequently take on the role of enforcing norms, aggressing against those who violate them and breaking up disputes between lower-ranking individuals (Boehm 1999).

The hierarchies that characterize primate groups are rarely static structures. Instead, individuals continually vie for control of resources. Higher-ranking individuals defend their privileged access to resources by detecting and punishing acts that threaten privileged access, while lower-ranking individuals attempt to engage surreptitiously in forbidden activities in order to secure a larger share of resources. Individuals move up in rank to the extent that they form alliances with dominants through the formation of reciprocal obligations. Rank within primate dominance hierarchies is acquired and maintained through dyadic aggression, and alliances typically determine the outcome (Harcourt and de Waal 1992; Uehara et al. 1994). Alliances are formed on the basis of reciprocal obligations, such as reciprocal grooming or food sharing (Schino 2007). Alliances are also terminated when an individual fails to reciprocate in giving aid, grooming, or food sharing (de Waal 1992). Cosmides’ social contract theory addresses the

reciprocal nature of these interactions. It does not address, however, the impact of social rank on reciprocation. The terms “despotic” and “egalitarian” have been applied to animal social groups to describe end points on a continuum of the degree of bias in which benefits are distributed (Vehrencamp 1983). A recent analysis of hierarchies falling on the extreme ends of this dimension indicated that the rate of reciprocity and prosocial behavior varies considerably as a function of the steepness of the hierarchy (Kaburu and Newton-Fisher 2015): In chimpanzee groups that show steep rank relationships, dominants provide more agonistic support than subordinates, males direct grooming up the hierarchy, and the rate of reciprocation of grooming is lower for dominants than for subordinates. These observations are best explained as strategies employed by subordinates to obtain rank-related benefits from dominants. In contrast, within shallow hierarchies, high-ranking individuals do not offer agonistic support more frequently than low-ranking males, and dominance rank does not affect grooming distribution, with males of similar dominance rank showing stronger reciprocity than those who hold more distant ranks. Even in steep hierarchies, other research has shown that among chimpanzees, for instance, dominants may trade meat for coalitionary support or mating, as long as they cannot obtain these commodities by force (Jaeggi and Gurven 2013). In fact, primatologists have noted that the most generously sharing individuals are often fully dominant (de Waal and Brosnan 2005).

Lower status individuals also frequently engage in deceptive behaviors that improve their access to resources (Byrne 1995). They conceal objects or behaviors from others by hiding them from view, acting quietly so as not to attract attention, avoiding looking at desirable objects themselves, and distracting attention away from a desired object (such as fruit) or forbidden behaviors (such as mating with non-dominants). For example, dominant males monopolize reproduction opportunities by aggressing against females and subordinate males who are caught socializing or consorting. Because of the high risks involved in such forbidden liaisons, females

and subordinate males often engage in deception, such as concealing their trysts from the view of dominants and suppressing their copulation cries (Kummer 1988; de Waal 1988).

Finally, the neocortex ratio expresses the relative volume of the neocortex compared to the volume of the rest of the brain. It correlates with the mean group sizes that characterize primate species, with larger group sizes corresponding to greater neocortical volume. This ratio correlates with the prevalence of tactical deception observed across primate species (Byrne 1995, pp. 219–221).

Developmental Psychology. Since the 1980s, developmental psychologists have used techniques borrowed from comparative psychology to investigate the cognition of preverbal infants and very young children. They have discovered that infants and toddlers possess an astonishing wealth of knowledge about agents and objects long before there is sufficient time to induce such knowledge from experience. The best explanation for this state of affairs is that these techniques have provided a window into human cognitive evolution, showing us the types of cognition that were shaped by evolutionary pressures.

Infants as young as 6 months of age infer the social dominance relationship between two competing individuals based on the size of the group to which they belong and expect individuals from a numerically larger group to get their way (Pun et al. 2016). By 10 months of age, they can transitively infer dominance relations, just as other primates do (Gazes et al. 2015). Yet, like other primates, children can perform object-based transitive reasoning only if they are extensively drilled on the object pairs upon which the inference is to be performed. Truly content-free transitive reasoning does not reliably appear until 6 years of age.

Status hierarchies are apparent in the playgroups of preschool children as young as 2 years of age (Strayer and Trudel 1984). As early as 3 years of age, preschoolers are able to infer dominance not only from physical supremacy but also from decision power, age, and resources (Charafeddine et al. 2015). They expect an individual who imposes his choice on another

to exhibit higher competence in games and to have more resources. Children also prefer to associate with and imitate high-status as opposed to low-status individuals (La Freniere and Charlesworth 1983).

Children also show a marked *precocity* for acquiring social norms and monitoring compliance with them (Cummins 2013a, b). By the age of 3 years, children's reasoning performance is characterized by a deontic advantage as large as that seen in adults: They rightly seek violations when testing behavioral compliance with a rule but wrongly seek confirmation when testing the truth of a rule, just as adults do (Cummins 1996b). Children as young as 3 years of age do not just follow social norms; they actively enforce them on others – even when serving as spectators rather than players in the game (Schmidt and Tomasello 2012).

The ability to deceive is closely tied to theory of mind, that is, the ability to understand that individuals have inherently private intentions, desires, and beliefs and will act accordingly (Bartsch and Wellman 1989). Deception relies on this ability because to deceive, individuals must understand their target's mental state – what the target knows, wants, or believes. Within the first year of life, infants engage in subtle manipulations that succeed in deceiving others at least temporarily, and the bulk of these deceptions have as their goal hiding activities that are forbidden by adults (dominants) (Reddy 2007). For example, they will hold eye contact with an adult in order to draw attention away from a forbidden activity, such as discreetly throwing disliked food or objects onto the floor. They will also do forbidden things quietly so as not to draw attention to their behavior, wait until a parent leaves the room before rushing to engage in a forbidden activity, and turn their backs or use their bodies to screen a forbidden activity or object from other's view (Reddy 2007). By the second year of life, infants can reason not only about the actions of agents who hold false beliefs but also about the actions of agents who seek to implant false beliefs (Scott et al. 2015).

Anthropology. The egalitarianism of small-scale societies is often misconstrued as an absence

of dominance motivations (or status striving) on the part of group members. Yet leaders in these societies may orchestrate collective actions that produce goods more beneficial to themselves and their kin (von Rueden and van Vugt 2015). Instead, small-scale society egalitarianism is better understood as an active leveling of would-be dominants through norms compelling humility and coordinated punishment of aggrandizers (Boehm 1999). These norms strongly impact decisions members of small-scale societies make in economic games. Henrich et al. (2005) conducted a cross-cultural study of decision-making in 15 small-scale horticultural, foraging, and pastoral cultures in Africa, South America, and Asia. Their results clearly showed a pattern of behavior best described as status seeking and alliance formation through gift giving, which is common throughout Melanesia. The authors concluded that economic behaviors emerge from “a set of basic human psychological mechanisms involving fairness and resource distribution, constrained in different ways by kinship, age, status, and other biologically meaningful variables.”

Behavioral Economics. A cornerstone of economic theory is that rational agents are self-interested agents. When making choices about allocations of resources, rational agents will choose to maximize benefits to themselves. More than a decade of research in experimental economics, however, has shown that people do not always behave this way, often choosing to be more generous or stingy than predicted by rational self-interest. In the dictator game, dictators have full control over allocation of a windfall resource between themselves and another individual. Rational dictators should keep all of the resource for themselves, but experimental results indicate that, on average, dictators freely give away about 15–35% of the resource to their partners (Camerer 2003). In the ultimatum game, one party proposes how to divide a sum of money, and the other party chooses whether to accept or reject the proposed division. If the offer is rejected, the entire sum is forfeit. From a rational standpoint, any amount (no matter how small) should be accepted since something is always better than nothing. But

results indicate that proposers tend to be more generous in their offers, with 40–50% comprising the modal range, while recipients tend to be choosy, with offers of less than 20% being routinely rejected. Here, proposers appear to behave strategically, taking into consideration which offers are likely to be acceptable to their partners.

Importantly, several studies have reported that perceived relative status strongly impacts behavior in both dictator and ultimatum games (Ball and Eckel 1996, 1998; Eckel and Wilson 2007; Hoffman et al. 1994, 1996). Dictators offer less to their partners when they are told that they scored higher on a trivia test than their partners did. Ultimatum proposers also offer less when they believe they ranked higher than their partners, and responders are willing to accept lower offers when they believe proposers ranked higher.

Neuroscience. In the last decade, studies involving fMRI and ERP technology have revealed broad brain regions that detect and process social dominance and social rank, indicating that recognition of relative social rank occurs quite rapidly – within 200 ms (Chiao et al. 2008). These regions include the amygdala, hippocampus, striatum, and various cortical networks such as the prefrontal and parietal cortices. The amygdala and anterior hippocampus have been implicated in tracking social rank but also in expressing signals that code for social rank (Kumaran et al. 2012). Additionally, it has been found that neurotransmitter systems, such as the dopaminergic and serotonergic systems, modulate and are modulated by the formation of the social hierarchy in a group.

Cognitive Psychology. When asked to monitor compliance with a social rule, adults are more likely to look for rule violations when they adopt a high-status position relative to the individuals whose behavior they are monitoring (Cummins 1998). But when engaged in reciprocal exchanges, adults instead exhibit noblesse oblige, that is, greater generosity and greater tolerance for non-reciprocation when they adopt a high-status perspective, even when the lower-ranking partner was described as having a higher income than the higher-status partner (Fiddick and Cummins

2001, 2007). This pattern of behavior has been reported among participants from seven countries that vary along hierarchical and individualist/collectivist social dimensions; participants were more tolerant of non-reciprocation when they adopted a high-ranking perspective compared with a low-ranking perspective (Fiddick et al. 2013). The best explanation for these status effects is costly signaling theory which states that costly, altruistic acts may benefit an altruist indirectly by establishing a “reputation” that enhances alliance formation, a factor that is crucial for acquiring and maintaining a high-status position (Bird et al. 2001).

Criticism of Dominance Theory

The main motivation for dominance theory is explaining the “deontic advantage” in human reasoning. But other interpretations of the “deontic advantage” have been offered that reject evolutionary accounts. Most of these explanations focus on studies employing the Wason card selection task in which participants are asked to choose which cards must be turned over to test the truth of a rule or compliance with the rule (Wason 1968). Oaksford and Chater (1994) have argued that people view the deontic (rule compliance) and truth-testing versions of these tasks in terms of optimal data selection and shift their strategies from maximizing expected information gain on the truth-testing version to maximizing expected utility on the deontic version. Manktelow and Over (1995) and Evans and Over (1996) also explain performance on the deontic version of the selection task by modeling it as a process in which subjects seek to maximize subjective expected utility. In the deontic version, reasoners are purported to construct a model of the rule along with possible outcomes and to evaluate these outcomes in terms of costs (negative utility) and benefits (positive utility). In contrast, on the truth-testing version of the task, reasoners purportedly try to maximize expected epistemic utility by choosing evidence that will reduce their uncertainty about some particular claim relative to another.

While researchers differ in terms of their explanations for marked performance differences on deontic and truth-testing reasoning tasks, the larger question is why people perform exceptionally well on the deontic version of the task regardless of general intellectual ability or level of education, while performance on the truth-testing version correlates positively with intelligence (Stanovich and West 1998). Is it something about the nature of the tasks, or is it something about the nature of human cognition?

Dack and Astington (2011; Astington and Dack 2013), among others, argue that the extant data on the deontic advantage cannot speak to the issue of innateness or evolutionary impact on cognitive architecture. Instead, they argue that expertise in deontic reasoning is due to experience: The ubiquity of social rules in everyday life leads to the development of deontic reasoning schemas. These ubiquitous encounters with social rules facilitate conceptual development during the preschool years through explicit instruction and social enculturation. The difficulty is that these explanations fail to address the fact that children are exposed to lies and falsehoods as frequently as they are to social rules (Heyman et al. 2009, 2013), yet they infer no efficient strategy for testing the truth of statements (Cummins 1996b, 2016c).

Conclusion

According to dominance theory, the evolution of social cognition was shaped by the continual need to survive within dominance (or status) hierarchies, the social organization that is ubiquitous in the societies of humans and nonhuman animals. Five main cognitive functions arose from the evolutionary pressures imposed by this social structure: rank discrimination, acquiring social norms, monitoring compliance with social norms, monitoring reciprocity, and flouting social norms through deception. Support for the theory comes from six sources: comparative psychology (particularly primatology), developmental psychology, anthropology, behavioral economics, neuroscience, and cognitive psychology.

Definition

Testosterone and cortisol are steroid hormones that have effects on dominance behavior and are in turn influenced by dominance-related social interactions.

Introduction

Dominance status is an important factor in the structuring of many animal and human societies.

Dominance is the state of having high social status relative to one or more group-mates, who react submissively to dominant individuals. High status within hierarchical societies provides important benefits to individuals, including priority of access to resources, enhanced influence over subordinates, and ultimately, increased fitness. Lower-ranking individuals are therefore often motivated to improve their position in the hierarchy, whereas higher-ranking individuals strive to maintain their current status. Dominance relationships are often established by fight or threat displays, perhaps most commonly observed during agonistic competitive interactions between group-mates. Dominance displays also function to maintain social rank, once it has been acquired.

Research into the biological factors that affect dominance in animal and human groups suggests that dominance behavior is importantly influenced by two steroid hormones, testosterone (T), a reproductive hormone, and cortisol (C), a stress hormone; concentrations of both these hormones can be measured in blood, saliva, urine, feces, or hair. Two axes in the body, the hypothalamic–pituitary–gonadal axis and the hypothalamic–pituitary–adrenal axis, produce T and C, respectively; each of these axes inhibits the other at several different levels. Together these axes create a complex network regulating aggressive and dominance behavior, although the direction and strength of these hormonal influences are still being assessed. Several hypotheses have been put forward to explain the relationship between dominance and these hormones in a wide variety of animals.

Cortisol and Dominance

The relationship between C and social dominance varies both across and within species (Creel et al. 2012). Several studies have indicated that socially dominant animals have relatively low concentrations of C, whereas subordinate individuals have relatively high C levels. Often, these differences are particularly striking during times of social instability. In other

species, however, dominant individuals have elevated C concentrations compared to those in subordinate animals. Thus, in some cases, it is stressful to be at the top of the social ladder, and in other cases, being at the bottom of the hierarchy is stressful. These differences probably reflect species-specific factors such as social organization, stability of the hierarchy, resource allotment, frequency of agonistic and conciliatory behaviors, and the ability of subordinate animals to avoid dominant individuals (Sapolsky 2005).

The Challenge Hypothesis

The “challenge hypothesis” (Wingfield et al. 1990) was originally proposed to explain intra- and interspecific variation in T secretion in birds in relation to aggressive, sexual, and parental behavior. Here we will focus on dominance and aggressive behavior, about which the challenge hypothesis predicts that behavioral stimuli and social context can alter endogenous hormone concentrations. Behavioral cues, such as territory establishment, agonistic “challenges” from males, and sexual behaviors from females, stimulate the secretion of T. In turn, this increase in T leads to a rise in territorial and mate-guarding aggression. By adjusting T production to the social environment, individuals can exhibit flexible behavioral responses that fit the specific challenge and can also avoid the fitness-reducing costs associated with chronically elevated T levels. A recent meta-analysis found that T was positively correlated with both dominance and aggressive behavior in mammals, although there was no strong pattern when observed across the diverse mating and parental care systems of all vertebrate taxa (Hirschenhauser and Oliveira 2006).

Archer (2006) applied the challenge hypothesis to humans, reasoning that T levels should increase in any competitive situation, particularly in males. In Archer’s meta-analysis, both men and women demonstrated a small but positive association between T and aggression, and a larger positive correlation between T and measures of dominance behavior such as toughness, leadership, and aggressive dominance.

The Biosocial Model of Status

Focusing on humans and other primates, the “biosocial model of status” supplements the challenge hypothesis by making explicit predictions regarding T in relation to changes in status (Mazur 1985). Like the challenge hypothesis, this model predicts that T concentrations change during competitive interactions, increasing in winners and decreasing in losers. T should rise shortly before a competitive encounter, increase further in winners at the end of the competition or after a rise in status, and decline in losers or after a reduction in status. Feedback between T and the dominance outcome reinforces a continuation of that behavior, such that these changes in T influence an individual’s future competitive behavior. Thus, this model suggests a relationship of mutually reinforcing feedback between T concentrations and social dominance.

Hormonal Correlates of Competition

Winner and/or loser effects have been observed across a wide range of animal taxa. Individuals that have recently won generally exhibit more aggressive behavior toward a new opponent and have a better chance of winning again (the winner effect), whereas individuals that have recently lost frequently display more submissive behavior and have a higher likelihood of losing again (the loser effect) (Hsu et al. 2006). In many species, the outcome of the competition influences T concentrations, with increased levels in winners and reduced levels in losers (Hirschenhauser and Oliveira 2006). In some species winning a contest is not sufficient to increase the probability of winning future contests unless the victory is associated with an increase in T (Carré and Olmstead 2015). Evidence for the physiological basis of the loser effect is more variable, although elevated levels of C are often discovered in individuals that have recently lost a fight (Hsu et al. 2006).

In humans, T rises in anticipation of a competition and increases during competition; these increases in T are higher during sports competitions than during nonphysical forms of competition

(Archer 2006). Athletic competitions are usually also associated with an increase in C in both men and women, regardless of the competition outcome. Winning an athletic competition is associated with an increase in T in both sexes across a variety of sports, although there is no consensus on the effects of losing on T (Casto and Edwards 2016).

However, the winner-loser effect is much more variable when evaluated across all types of human competition, from laboratory paradigms to political elections, including athletics. In a recent review, Carré and Olmstead (2015) found that, although many studies reported that winners had elevated T levels relative to losers, nearly as many studies failed to find this effect; other reviews have found similarly inconsistent results in regard to C (Casto and Edwards 2016). This heterogeneity in results is possibly due to individual differences in personality and contextual differences between competitions. In humans, the T response to competition is more important than the actual contest outcome in predicting future competitive and dominance behavior. Thus, a postcontest rise in T predicts increased competitive behavior in the future, whereas a decrease in T predicts less competitive behavior in both winners and losers alike (Carré and Olmstead 2015).

The Dual-Hormone Hypothesis

One probable explanation for the variable findings described above is that T and C interact to regulate dominance, such that neither hormone alone predicts competitive behavior. The “dual-hormone hypothesis” instead suggests that the positive relationship between T and dominance pertains only to individuals with low levels of C, with C blocking the effect of T on dominance (Mehta and Josephs 2010). Thus, T should only increase dominance behavior and encourage higher status when C is low. There has been significant empirical support for the interaction between C and T in both men and women with respect to leadership, social status, and risk-taking in both athletic competitions and laboratory paradigms (Casto and Edwards 2016). Although there have been a few

studies in nonhuman animals of the competition dynamics posited by the dual-hormone hypothesis, it is evident that T and C levels vary between dominants and subordinates according to each species’ social system, reproductive strategy, and the allostatic load distribution within the dominance hierarchy.

Conclusion

Research has shown that dominant and competitive behavior is associated with changes in both T and C. In mammals, T positively correlates with dominance and with aggressive behavior, whereas C and its relationship to dominance vary across and within species. The challenge hypothesis, one of several put forward to explain hormone-behavior relationships, suggests that social and environmental factors affect changes in T concentration. The biosocial model of status expands the challenge hypothesis to predict that T concentrations should increase in winners and decrease in losers in human competitions, allowing individuals to quickly adjust to changes in their social status. In competitive situations, C has also been shown to moderate the psychological effects of T, and more recent research has suggested that the relationship between T and dominance is only true for individuals with low levels of C. This dual-hormone hypothesis may explain individual differences in dominance behavior that remain unexplained by single-hormone studies of dominance.

From an evolutionary standpoint, these divergent hormonal responses may allow for rapid adjustment in social behavior relative to changes in the social environment. In winners, the increase in T may promote the competitive, aggressive behavior necessary to defend their status, and the decreased T levels in losers may promote submissive behaviors that permit avoidance of physical injury and prevent further loss of status. Overall, the short-term changes in hormone concentrations modulate social behavior and dominance and likely have far-reaching fitness implications for individuals. This idea remains relevant as researchers work to develop a deeper understanding

of the variety of hormonal mechanisms that underlie dominance and aggression in human and animal societies.

Dominant Acts Expressed (Buss 1981)

Zachary H. Garfield
Department of Anthropology, Washington State University, Vancouver, WA, USA

Synonyms

[Aggression](#); [Power](#); [Sex differences](#); [Status](#)

Definition

Psychological research suggests men and women employ sex-specific strategies for expressing dominance, and dominant acts are perceived differently based on the sex of the actor. The nature of sex differences in dominance-based behavior, variation in personality and dominance, and ethnographic accounts of dominance in leadership positions are discussed.

Introduction

The role of dominance in the formation of hierarchy is an ancestral feature of social organization

humans share with nonhuman primates as well as social animals generally. As a strategy for achieving influence, dominance is likely a cross-cultural universal, yet there are stark sex differences and cultural variation in the universal expression of dominance.

Dominance consists of gaining authority through the use of coercion, fear, aggression, or agonistic threats by social superiors to subordinates (Cheng et al. 2010; Henrich and Gil-White 2001). Patterns of deference behavior follow a semi-stable ranking in a transitive and linear fashion. Within human social hierarchies, there is immense variation in the expression of dominance, and the formation of dominance hierarchies does not necessarily involve direct aggression. Culture, ecology, personality, age, and sex can all influence the ability of and means by which an individual pursues a dominance-based strategy for achieving influence within a group.

Buss (1981) investigates the expression of dominance and the evaluation of dominant acts in reference to established psychological models and reports sex differences in both the desirability and expression of dominant acts. Over the past 35 years, dominance, contrasted with prestige, has become a prominent theoretical framework in models of social status and hierarchy (see Cheng et al. 2014). Here Buss' seminal study is reevaluated, and findings are framed in the context of relevant contemporary literature.

Conceptualizing Variation in Dominance

Symbolic and complex cumulative culture presents humans with a range of opportunities for expressing dominance, and individuals can adjust dominance-based strategies for specific situations. Variation in phenotypic expression and personality type can render certain expressions of dominance more amenable for different individuals. For example, dominance can be expressed very directly relying on physical size and agonistic threats or more subtly through prosocial behavior and tactful displays. Buss (1981) tested the expression of dominance in reference to Bakan's (1966) dualistic model of human existence, which suggests human existence – behavior – can take one of two forms; individuals can act agentically,

or in masculine fashion with egocentric aims, or individuals can act communally, or in feminine fashion with group goals shaping behavior. In this context, Buss (1981) addresses whether there is a sex difference in the desirability of dominant acts, if dominant acts are perceived to be more desirable when performed by a male, if males and females differ in frequency of performing dominant acts, and if males and females differ in regard to the nature of expressing dominant acts. In addition to identifying important sex difference in the expression of dominance, Buss (1981) seeks to provide evidence counter to the stereotype that dominant behavior is an exclusively male trait. Following Bakan's model, Buss (1981) predicts that the expression and evaluation of dominant acts by males will follow the agentic mode, whereas the evaluation and expression of dominant acts by females will follow the communal mode. Buss (1981) tests these predictions using a two-study design and a sample of undergraduates rating 100 dominant acts on their social desirability and a self-report measure of how often they performed them.

The Expression of Dominance

Despite individual variation in the expression of dominance, evidence suggests males and females have sex-specific adaptations for expressing and assessing dominant behavior. Buss (1981) found males rated egotistic and manipulative acts as more socially desirable than females. Similarly, females rated prosocial, group-centric expressions of dominance as more desirable than males. This profound sex effect reveals men consider more self-serving and egotistical dominant acts as more desirable than women.

To investigate if perceptions of dominance manifest in expressions of dominance, Buss (1981) uses psychometric measure of dominance in comparison to self-report measures of the performance of dominant acts. Among men and women, those who score high on psychometric measures of dominance tend to also report greater frequencies of performing dominant acts. However, the study revealed sex-specific trends in reported expressions of dominance. Dominant men reported performing egoist, self-serving acts of dominance at greater

frequencies than women, whereas women's reported acts of dominance were more likely to be prosocial and group focused. According to Buss (1981), the expression of dominance among men is more likely to serve immediate individual level goals; for women, dominant behavior is more likely to increase within-group cohesion.

Buss (1981) revealed women do engage in dominant behavior but tend to do so in a gendered way. Egoistic and prosocial dominance behaviors represent two strategies for achieving social influence within a group, and despite general sex-specific trends, the two strategies are not mutually exclusive or necessarily sex specific. Hawley et al. (2008) suggest there is less distinction between male and female expressions of dominance than previously described and both males and females employ egoist and prosocial strategies for achieving social influence, independent of aggressiveness. Using a sample of German children and peer-report, self-report, and psychometric data, Hawley et al. (2008) measured the propensity to engage in coercive or prosocial strategies, the ability to control group resources, individual dominance and aggression, and social standing. Similar to Buss (1981), key sex differences emerged.

Among children, boys are more likely to value social influence, employ coercive and aggressive strategies in attaining influence, and report success in their attempts at gaining social influence (Hawley et al. 2008). This distinction also manifests in peer reports with children reporting boys are more controlling, coercive, and aggressive than females. However, contrary to perspectives emphasizing sex differences in expressions of dominance, several important similarities were documented between boys and girls scoring high on measures of dominance and resource controlling ability.

Children demonstrate a preference in play for bistrategic controllers or those who employ both prosocial and coercive strategies of control (Hawley 2003). Both males and females are perceived as equally effective at controlling resources when using both coercive and prosocial strategies (Hawley et al. 2008). Additionally, bistrategic controllers are equally likely to be male or female, limiting the ability of males to disproportionately

control group resources and dynamics when prosocial strategies are considered (Hawley et al. 2008). However, when overt physical aggression is the principal mechanism by which individuals strive to achieve social influence, females are at a disadvantage. Considering relational aggression, girls are perceived to out rank boys (Hawley et al. 2008), a trend that continues across development (Hess and Hagen 2006). These sex differences are widely supported in the psychological literature (Campbell 2002) and in at least one study among hunter-gatherers (Hess et al. 2010).

Females are able to compete with males during childhood through employing a bistrategic approach to social influence. A similar phenomenon emerges among postmenopausal women. Several ethnographic accounts reveal that after their childbearing years, women in small-scale society are more likely to surface as major political agents and achieve positions of leadership in prosocial arenas. This has been termed a "coming of age" for women's sociopolitical influence (Brown and Kerns 1985). Traditionally, during their reproductive years, women are limited in their ability to pursue positions of social influence, and their ability to express social dominance through coercive or prosocial strategies is ineffective.

Dominance and Personality

The propensity to pursue a dominance-based strategy is not solely related to physical size and aggression. Whereas Buss (1981) related the expression of dominance to agentic and communal behavior, contemporary studies have investigated the expression of dominance in the context of variation in personality. In a predominately female sample of undergraduates, Cheng et al. (2010), using a series of psychometric measures, contrast hubristic pride, which is driven by antisocial behavior, arrogance, and conceit, with authentic pride, which is driven by individual accomplishments, success, and confidence. Based on self-report measures, hubristic pride was positively and strongly related to dominance as predicted. Unexpectedly, authentic pride demonstrated a weak positive relationship to dominance as well, independent of other relationships (Cheng et al. 2010). Additionally, dominance was positively related to narcissism, aggression, and

extraversion and, to a lesser degree, conscientiousness. Conversely, dominance was negatively associated with agreeableness, social acceptance, and self-esteem (Cheng et al. 2010).

In the described study, the authors do not focus on sex differences. These results reveal patterns in the expression of dominance across personality types independent of sex. Despite variation in the expression of dominant acts, males and females more prone to pursue dominance-based strategies of social influence are likely to share common personality profiles.

Cultural Variation in the Expression of Dominance by Males and Females

The expression of dominance and dominance-based strategies for achieving positions of social influence are very likely universal features of an inherited leader-follower psychology. However, ecological and sociocultural features contribute to variation in the expression and utility of dominance-based behaviors in unique ways for males and females. Contrasting ethnographic examples from egalitarian populations, or populations which lack inherited status differences, have little wealth disparity and are generally characterized by greater gender equality, with stratified populations, which are characterized by graded differences in inherited status and wealth and demonstrate increased gender inequality and reveal the influence of cultural systems on sex-specific expressions of dominance.

In egalitarian societies, leaders and high status individuals have limited direct authority over subordinates, and overly assertive expressions of dominance can be subverted through group-wide resistance, deposition, or physical retaliation (Boehm 1999). Egalitarian societies tend to lack expressions of dominance in sociopolitical organization and among the Mbuti, Turnbull (1965:187) relates that, "it is plain, then, that while any movement toward individual authority, conscious or otherwise, is sharply countered, and while individual authority is virtually nil, there is nonetheless a clear basic framework to support the values of the hunting band. There is the division of leadership, according to field, throughout the entire band, yet there is the midcamp site from

which anyone may harangue all present." With dispersed and contextual leadership, Mbuti society accomplishes effective organization yet maintains and promotes an openness of dissent. The ability of any one individual to effectively employ dominance-based strategies in leadership positions is limited.

Within the egalitarian system of the Iban, men engage in ruthless between-group competition and head-hunting which leads to within group positions of influence based on respect but also fear, intimidation, and threats of physical aggression. Counter to these egoist expressions of dominance, women are expected to provide a more prosocial service among couples with considerable social influence. Sandin (1967:56) describes, "wives of these heroes should also try to excel other women in various skills. Without these qualities, they could neither have the position to receive the human heads which their husbands hunted. . . nor could they become leaders of other women if they are bad, greedy and jealous. All women who are married to such prominent persons should, therefore, initiate good deeds in order to match with the courage and qualities of their husbands." Egalitarian societies both reward and resist expressions of dominance. Dominance-based strategies can secure group interests in between-group competition but must be resisted or balanced with prosocial investments in the context of within-group collective action and social organization.

The emergence of inequality and social stratification is linked to an increase in dominance-based strategies for social influence. With an increase in monopolization over resources and social influence and a reduction in equality, leaders are able to expand the domains through which dominance can be expressed (Kaplan et al. 2009). By exploiting followers and exercising dominance across social relationships, including kin groups and in marriage patterns, in economic systems, using organized military forces, and across broad ideological values, leaders effectively maintain and control positions of authority and are able to pass on these positions to their offspring (Earle 1997). Amhara chiefs are known to strategically and preemptively act to

maintain their social control, and in one example, it was noted that the chief, “expects to see his tenant-followers quite often. If they stay away for more than a reasonable period of time, he will suspect that they are plotting against him or currying the favor of some other important man” (Hoben 1963:182). Cultural systems and socio-political organization grant chiefs excessive power and ample opportunities to employ dominance-based strategies. Among the Bemba, Richards (1940:106) describes, “the sanctions for a chief’s authority are numerous, and they were still greater in the old days. . .much of his power also rested in the old days on force. A chief practised savage mutilations on those who offended him, injured his interests, laughed at him or members of his family, or stole his wives. A number of these mutilated men and women still survive in Bemba country today. Command over the army and over the supply of guns also lays in the chief’s hands, and there is no doubt that the greatness of the Bena nandu rested to a large extent on fear. The people explain that the royal family were named after the crocodile because ‘they are like crocodiles that seize hold of the common people and tear them to bits with their teeth’.” With authority over wide social domains and the sanctioned use of force at their disposal, leaders in highly stratified societies maintain near divine positions of power and wield this power absolutely, instilling fear in followers through threats, aggression, and deadly force.

Though opportunities for dominance-based strategies for achieving social influence among women are rare in stratified traditional societies, they are not universally absent. Among the matrilineal Trobriands, Austen (1940:272) mentions that, “Botabalu lives in a high-chief’s house, and has women and girls for her companions, who keep the house clean and tidy. . .she is a stout woman and does not walk about. Most of her time is spent in the village, and because she is a great chieftainess, with many kinsmen and numerous villages under her rule, she is greatly feared by all.” In the context of hereditary social stratification, female leaders, though to a lesser degree than males, also employ dominance-based strategies to achieve and maintain positions of influence.

Conclusion

Buss (1981) provided a framework for understating and investigating sex differences in dominance behavior. Most notably, males tend to use dominance-based strategies to achieve personal, egocentric goals, whereas females tend to use them to achieve group-level goals.

Further research in the field both supported this distinction and revealed caveats. Among Western children, when both dominance-based and prosocial strategies are considered, there is little distinction between high-ranking males and females (Hawley et al. 2008). Additionally, the personality profiles of males and females who employ dominance-based strategies in social interactions are likely very similar, with both trending toward narcissism, extroversion, and aggression (Cheng et al. 2010).

Across a diverse range of leaders in traditional societies, expressions of dominance are associated with positions of social influence. However, the nature of expressions of dominance varies greatly between egalitarian and stratified societies and between sexes. Cultural context and sociopolitical organization influence the viability of specific types of dominance-based strategies, but do not completely prevent them.

The dominance model adopted from ethology and animal social hierarchies has been incredibly influential within the social sciences investigating leadership, status competition, and social influence. Buss’ seminal work remains an important foundational study in this field.

Donner Party Disaster: Scarce Resources and Illness

Andrew M. Holub

Department of Psychology, Oakland University,
Rochester, MI, USA

Synonyms

Donner-Reed Party; Group mortality during environmental stress

Definition

The Donner Party disaster is one example of how children, the elderly, males, and individuals in smaller kin groups tend to die at the highest rates during periods of scarce resources and illness.

Introduction

Evidence taken from the records of historical disasters, such as the abortive Donner Party expedition in the American West, suggests that periods of scarce resources and illness within a population generally produce varying mortality rates between its constituents. Preadolescent children (including and especially infants) and the elderly are usually the first members to perish. Within adult populations at lower risk for death, males die at higher rates and more quickly than females. Further, larger family groups produce higher survival rates than smaller groups.

Factors Predicting Mortality

In his review of the records from the Donner Party, Grayson (1993) provided confirmatory evidence that scarce resources predict illness and differential survival patterns in human groups such that mortality during environmental duress generally follows a prescribed plot. Typically, a curvilinear pattern is observed in mortality, with children and the elderly dying more quickly, and in greatest numbers. Death rates are usually highest between 1 and 5 years of age, decreasing until around age 35 years, at which point mortality rates begin to increase again. This trend has been well documented in other historical disasters, such as during the 1974–1975 famine in Bangladesh (Watkins and Menken 1985). Thus, age is a major predictor of survival during times of famine and climatic hardship.

Similarly, sex differences have been observed in survival patterns during periods of environmental stress. Females tend to have higher survival rates than males, which also reflects the general longer life span of females relative to males worldwide (World Health Organization 2014). In fact, cross-culturally, males have near universally higher mortality rates at all periods of life, beginning at infancy (e.g., Pongou 2013). Many behavioral and proximate factors may contribute to higher mortality among males, such as the tendency toward

aggression and risk-taking behavior (i.e., young male syndrome; Wilson and Daly 1985). These dispositions seem to be exacerbated during periods of scarce resources and illness.

One biological difference proposed to be related to the disparity in survival between sexes is body fat reserves and metabolic rates. In general, females have higher fat reserves as well as lower metabolic rates than men, meaning their lower energy requirements and higher energy reserves may help buffer against starvation. Although men may be thus disposed to higher mortality, this model may be inadequate to completely explain differential survival patterns seen during periods of duress (Speakman 2013). Males are also more often exposed to grueling or dangerous conditions, causing greater risk for fatality especially in times of scarce resources (Grayson 1993). These conditions can include performing more labor-intensive (and thus calorically costly) tasks, such as clearing vegetation impeding travel as in the Donner Party, and can also carry risk of physical injury. Thus, some combination of biological disposition and proximate factors likely combine to produce a higher mortality rate among male members of communities facing environmental duress. Evidence from the Donner Party supports this conclusion, where males died at about twice the rate of females (Grayson 1993).

Finally, larger kin groups may provide a buffer against mortality during periods of scarce resources. Because cooperation can increase resource procurement and allocation within a group, and since cooperation is more likely among genetically similar individuals (e.g., West et al. 2002), even if these individuals are not kin (Sinervo and Clobert 2003), it follows that larger kin groups would also promote cooperation and, consequently, survival. This pattern was found among the Donner Party, with the surviving members travelling with larger average kin groups than deceased members (Grayson 1993). When resources are scarce, cooperation may be fostered by living among a larger group of genetically similar individuals, which may, in turn, provide social support in many forms such as sharing food,

nursing when injured, morale, and even higher immune system functioning (Grayson 1993).

Conclusion

When human groups are exposed to hardships, including disease and lack of resources, elderly and children tend to die first. Further, men tend to perish at much higher rates than women. It is proposed that the differential survival pattern between the sexes is due to many causes, including differences in body composition, caloric expenditure, and more frequent exposure to pathogens and dangerous activities. Finally, larger kin groups may buffer the risks posed to members of a community struggling against environmental hardships.

Dorsal Stream, The

Robert L. Whitwell

Department of Psychology, University of British Columbia, Vancouver, BC, Canada

Synonyms

[Dorsal visual pathway](#); [Superior longitudinal folliculus](#)

Definition

A parallel, hierarchically organized series (i.e., “stream”) of interconnected cortical structures in the occipital and posterior parietal cortex (PPC).

Introduction

The dorsal visual stream refers to a parallel series of cortico-cortical projections that arise chiefly from extrastriate visual areas of the occipital cortex, which innervate structures in and around the intraparietal sulcus (IPS) of the PPC. Many cortical structures of the dorsal visual stream are

reciprocally connected, send horizontal and feedback projections to structures within the same level and those within lower levels of the hierarchy, and show close homologies across human and nonhuman primates (Kravitz et al. 2011). Dorsal stream structures, like all others in primate cortex, are typically delineated according to their morphology, connectivity, and functional properties along microscopic and macroscopic scales of observation. However, unlike cells in “early” areas of the occipital cortex, visually-sensitive cells in the PPC, including those structures comprising the dorsal stream, possess relatively large receptive fields and the retinotopic organization of dorsal stream structures in the PPC is not as prominent. Furthermore, many cell responses in the dorsal stream require some level of volitional task engagement that involves the movement of effectors, such as the eyes or upper limb, or somatosensory stimulation of different parts of the body.

Subcortical Visual Input to the Dorsal Stream

Geniculostriate Visual Pathway

The dominant source of retinal input into both the dorsal and ventral streams comes through early visual cortex via the dorsolateral geniculate nucleus (dLGN). The dLGN receives visual input directly from retinal ganglion cells and indirectly via another direct recipient of retinal ganglion cell input, the superior colliculus (SC). Visual input from the dLGN to the occipital cortex arises from different populations of neurons. The best studied of those populations are the parvocellular (P) and magnocellular (M) cells, which occupy different layers of the dLGN (Kaplan 2004). Relative to P neurons, M neurons possess faster conduction velocities and their responses are more transient. Furthermore, M neurons are largely insensitive to chromatic difference, possess larger visual receptive fields, and are more sensitive to low-contrast visual stimuli (Kaplan 2004). The M and P cells send parallel convergent and divergent projections to striate (primary) visual cortex (V1). This pattern of connections continues on

through the many extrastriate cortical areas, forming parallel, though interconnected, subpathways within the dorsal and ventral streams (Ferrera et al. 1994; Kaplan 2004). The dorsal stream predominantly receives input from the M subpathway, whereas the ventral stream receives a more balanced input from the P and M subpathways (Ferrera et al. 1994). A major target of the M pathway are cells in layer 4Ca in V1, which send projections to cells in layer 4B in the same area. Neurons in layer 4B are strongly connected to two of the major “tributaries” to the dorsal stream, V5 and V6 (Ferrera et al. 1994; Gamberini et al. 2015).

Extrageniculostriate Visual Pathway

A second visual pathway to the dorsal stream involves the SC and pulvinar. The medial, central, and posterior nuclei of the inferior subdivision of the pulvinar receive direct visual input from retinal ganglion cells. The posterior and central-medial nuclei of the inferior pulvinar receive a secondary source of retinal input via the superficial layers of the SC. The medial, central-medial, and posterior nuclei of the inferior pulvinar project to extrastriate visual cortical areas that are located in and around the posterior middle temporal sulcus, including V5. The central-medial nucleus of the inferior pulvinar projects to another dorsal stream tributary V3A (Kaas and Lyon 2007).

Extrastriate Visual Cortical Area “Tributaries” to the Dorsal Stream

The extrastriate visual areas that send major projections to PPC structures of the dorsal stream are V3, V3A, dorsal prelunate gyrus (DP), V5, and V6 (see Fig. 1). V3 is a heavily-myelinated region that occupies the fundus of the lunate sulcus (LS) extending medially into the occipital-parietal sulcus (OPS). V3 lies in the posterior bank and fundus of the LS. V3A lies anterior to V3 on the anterior bank of the dorsolateral aspect of the LS and on toward the juncture of the LS and OPS. Both V3 and V3A receive visual input from V1 and V2. V3A predominantly projects to dorsal

Dorsal Stream, The, Fig. 1 Dorsal stream structures in the occipital and posterior parietal cortex and their connections to motor and premotor cortical structures in the frontal lobe. Not shown are the connections that involve V5 and its satellites, a dorsal stream tributary structure buried

in the caudal aspect of the superior temporal sulcus. Two major frontoparietal pathways of the dorsal stream, the dorsal and ventral premotor connections, are color coded blue and green, respectively

stream structures, whereas V3 innervates structures in both the dorsal and ventral stream (Felleman et al. 1997). V5 is located in the posterior aspect of the superior temporal sulcus and is characterized by dense myelination and its reciprocal connections with V1. V5 is part of a complex of additional neighboring visual areas which include the medial temporal sulcus (MST) and the fundus (floor) of the superior temporal sulcus (FST; Born and Bradley 2005). Area V6, another densely myelinated area, is located in and around the juncture of the OPS, IPS, and the LS, occupying the fundus and lower anterior bank of the OPS and posterior to the medial bank of the IPS toward the medial wall of the occipital cortex. Approximately half of its connections are with V1, V2, V3, and V3A; the remaining connections are with dorsal stream structures in the inferior and superior parietal lobule (IPL and SPL, respectively). There are no known direct connections between V6 and any ventral stream structures. Similar to V5, the heavy V1 projection to V6 originates in the M-dominant layer 4B (Gamberini et al. 2015). Thus, the connections of areas V3A, V5, and V6 can deliver visual input relatively quickly to two subpathways in the dorsal stream of the PPC, a dorso-lateral pathway in the IPL and a dorso-dorsal pathway in the SPL.

Reciprocal Subpathways Between Premotor Cortex and the Posterior Parietal Cortex

Dorso-Lateral Pathway

The dorso-lateral pathway is comprised of a number of structures in the IPL and IPS. The lateral surface of the IPL is parcellated along a posterior-anterior axis into areas Opt, PG, PFG, and PF. Medial to PG on the lateral bank of the IPS sits area LIP, and medial to PFG and PF, again on the lateral bank of the IPS but anterior to LIP, sits area AIP (Rizzolatti et al. 1998). Generally, each area within the IPL is strongly reciprocally connected with their immediate neighbor and less well connected with IPL areas beyond that neighbor. Areas PG, PFG, and PF are heavily interconnected with the parietal operculum, but Opt is not. LIP is not connected to its medial neighbors PG or PFG (Rozzi et al. 2006). LIP is reciprocally connected with its anterior neighbor, AIP. AIP is well interconnected with its neighbors PF and PFG. V3A sends a major projection to LIP and a minor projection to the ventral bank (fundus) of the IPS (VIP) (Nakamura et al. 2001). V5 and MST project to VIP and to Opt (Born and Bradley 2005; Rozzi et al. 2006). V6A projects to areas PG, Opt, and LIP (Gamberini et al. 2015).

The IPL structures of the dorso-lateral pathway form a ventral-premotor (PMv) cortical circuit. PMv lies posterior to the inferior branch of the arcuate sulcus and anterior to primary motor cortex (F1). PMv is comprised of two major subregions positioned along dorsoventral and rostro-caudal axis, F4 and F5, both of which are reciprocally connected with F1 (Rizzolatti et al. 1998). Areas PF and PFG are more heavily reciprocally connected with F5 than with F4 (Rozzi et al. 2006). Areas F5 and PF possess mirror neurons that respond to object-directed grasps performed by the self and those performed by others (Rizzolatti et al. 1998). AIP, along with its medial neighbor, PEip in the SPL, is predominantly connected to F5, whereas VIP is predominantly connected with F4 (Rizzolatti et al. 1998). LIP is reciprocally connected with the supplementary eye fields of F7 and the frontal eye fields, both of which are premotor structures in the frontal cortex (Rizzolatti et al. 1998; Nakamura et al. 2001).

Dorso-Dorsal Pathway

The dorso-dorsal pathway is comprised of a number of structures in the SPL and the medial bank of the IPS (MIP). V6A receives much of its visual input from V6 and is a major input node to its neighboring dorsal stream structures in the SPL which includes the medial bank of the IPS (MIP), area PE, which occupies much of the dorsal SPL, and the mesial side of area PG (PGm) anterior to V6A (Gamberini et al. 2015). Although the dominant PPC projection of V3A is to LIP, it also projects to the medial bank of the intraparietal sulcus (MIP). V6A projects to MIP, PGm, and the posterior subregion of PE (caudal PE or PEc). PEc is reciprocally connected to the neighboring somatosensory-related subregion of PE, located anterior to PEc, and the posterior cingulate area on the mesial PPC (area PEic; Gamberini et al. 2015).

SPL structures of the dorso-dorsal pathway form a dorsal-premotor (PMd) cortical circuit. PMd is located above the superior branch of arcuate sulcus and is comprised of two major subregions along an anterior-posterior axis, F7 and F2. PMd is reciprocally connected with F1 (Rizzolatti et al. 1998). SPL area PGm is reciprocally connected with F7,

whereas SPL areas PEc, PE, and MIP are reciprocally connected with F2 (Gamberini et al. 2015; Rizzolatti et al. 1998). Area PE is also reciprocally connected with primary motor cortex, area F1 (Rizzolatti et al. 1998).

Function

Many dorsal stream structures contain sensory, motor, and sensorimotor cells. Sensory cells are often sensitive to motion, orientation, or shape, whereas motor cells are often sensitive to different configurations of particular effectors such as the eyes, mouth, arm, wrist, or hand. For example, the response of some cells in V3A, V6A, and LIP depend on the position of the eyes in their orbit (Gamberini et al. 2015). Sensorimotor cells are often sensitive to both sensory and motor task features. Cells in areas V5 and V6 are sensitive to the direction, orientation, and speed of moving stimuli (Born and Bradley 2005; Gamberini et al. 2015). Cells in VIP are sensitive to stimuli moving toward or away from the viewer, arm movements toward and away from the body, and tactile stimulation to particular areas of the face (Rizzolatti et al. 1998). Cells in V6A are sensitive to the arm and hand movements performed when reaching for targets or grasping objects (Gamberini et al. 2015). Cells in AIP is sensitive to particular combinations of object shape and the hand and finger configurations recruited during grasping (Rizzolatti et al. 1998). Cells in the haptic areas PE and PEc are sensitive to combinations of joint configurations and tactile stimulation and are thought to provide F1 with information about body position necessary for the control of limb and body movement (Rizzolatti et al. 1998).

Conclusion

The dorsal stream is a hierarchical network of parallel cortical structures in the occipital cortex and PPC of the primate brain and receives major sensory input from visual and somatosensory cortex. Proposals concerning the nature and content of the operations performed in the dorsal stream

have been an area of active research for decades. Contemporary accounts focus on a number of different roles which are perhaps best summarized as *sensorimotor* and *sensorispatial* and would include goal-directed and object-interactive movements, spatial navigation, spatial working memory, action observation and recognition and movement planning (Kravitz et al. 2011; Rizzolatti et al. 1998).

Definition

Douglas Kenrick is a president's professor of social psychology at Arizona State University (ASU). He received a BA in psychology from Dowling College (1970) and a PhD (1976) in social psychology from Arizona State University under the tutelage of Robert Cialdini. Kenrick then served as an assistant professor of psychology at Montana State University before coming back to ASU. In 2018–2019, Kenrick served as president of the Human Behavior and Evolution Society. He has authored over 200 highly cited academic articles, 2 textbooks, and 2 popular books – *Sex, Murder, and the Meaning of Life* (2011) and *The Rational Animal* (2013, with Vlad Griskevicius) – as well as numerous edited volumes and invited book chapters. He is well

known among colleagues, students, collaborators, and anyone who has attended any of his talks, as being extremely insightful and funny. His wit and guts are undisputedly unmatched by any academic. In a now-legendary 2000 Human Behavior and Evolution Society plenary presentation, Kenrick delivered the entire 45-min talk in a deeply-southern Baptist preacher's accent and left a standing-room-only audience rolling with laughter in their seats and in the auditorium aisles.

Introduction

A favorite Kenrick quote is from Oscar Wilde, "We are all in the gutter but some of us are looking at the stars." A glimpse of his past indicates how a particular fondness for this quote may have come about. Douglas Kenrick was born in Queens, New York, into a family and environment hardly befitting to a future eminent scholar. As Kenrick openly recounts, his friends were switchblade-carrying greasers, and his father and brother both rightfully earned places in Sing Sing maximum security prison. Kenrick himself avoided life imprisonment by keeping in check his fantasies about killing his stepfather (but later used insights gained from this experience to investigate homicidal fantasies; Kenrick and Sheets 1993). He was, though, expelled from two high schools and put on academic probation at a community college. Somehow, in the midst of this unpromising life path, Kenrick developed a determination to break from family tradition and environmental influences and developed a keen interest in academics.

In this entry, we cover some of the many areas in which Kenrick has contributed important insights.

Personality

In his earlier work, Kenrick published an influential paper addressing a major debate on personality and the situation and how personality traits do actually meaningfully predict behavior (Kenrick and Funder 1988). Another paper challenged the

presumption that personality traits were weak predictors of behavior, by showing that traits which people rated high in self-rated observability and consistency yielded high agreement among self, parent, and peer ratings (Kenrick and Stringfield 1980).

Age Preferences

Together with former graduate school classmate Richard Keefe, Kenrick published several papers detailing people's minimum and maximum age preferences as indicated in their personal advertisements (Kenrick and Keefe 1992). They found that while women of all ages tend to look for mates at their own age or up to a few years older, men tended to want mates who are increasingly younger compared to their own age. Marriage statistics, as Kenrick found, fit this pattern quite nicely. Of particular note, teenage boys found women older than them to be most attractive, despite that those women did not have any interest in them (Kenrick et al. 1996). This finding countered the sociocultural notion that age preferences reflect men wanting to control women and younger women are simply easier to control. Instead, the entire pattern of findings on age preferences was consistent with an evolutionary psychological explanation that sex differences in age preferences reflect males having evolved to value female fertility and reproductive value, which peaks at age 23, and females having evolved to value men's social status and resources, of which older men have more.

Mate Preferences

Aside from age preferences, Kenrick has also investigated mate preferences for other traits, finding support for an important qualification on applying parental investment theory to humans. Using a minimum percentile preference paradigm, Kenrick investigated mate preferences across various types of relationship durations (Kenrick et al. 1990, 1993). Of particular note, he found that while men and women tend to have

similarly high minimum requirements across various types of relationships for traits like intelligence, they differ sharply when the relationship is purely sexual. That is, while women retain their high standards, men relax their standards considerably. As Kenrick pointed out, this sex difference reflects minimum differences in obligatory parental investment (Trivers 1972), where women but not men bear potential costs of pregnancy so women have evolved to be more selective and cautious than men for casual sexual partners. However, when men and women have evolved to invest similarly high as in committed, long-term relationships, both sexes are equally selective about their partners.

Another interesting and relevant line of work featured contrast effects. That is, when men view pictures of attractive, naked women – as in *Playboy*, *Penthouse*, or *Hustler* centerfolds – they subsequently find normal people and their own mates to be unattractive (Kenrick et al. 1989). Importantly, such effects are not limited to nude erotica, and the implications extend beyond high school boys giving lower ratings to their peers or wife. In a series of insightful follow-up studies, Kenrick and colleagues found that when exposed to facial photos of attractive women, women feel worse about their own mate value, and men feel less committed to their current partners. Similarly, when exposed to descriptions of socially dominant men, men feel worse about their own mate value, and women feel less committed to their current partners (Kenrick et al. 1994; Guttieres et al. 1999).

Together, these findings support the idea that people's view of themselves, their mating standards, and their relationship commitment, are indexed on – and can be sabotaged by – the perceived value of people in their environment. Furthermore, what constitutes value is sex-differentiated according to what traits are most adaptively beneficial to have in oneself as well as in one's partner. While this process would have been adaptive in the ancestral environment where anyone that one encountered was an actual potential mate or competitor, in the modern world, it leads to problems. Specifically, we now encounter thousands of still or moving images of beautiful

models and individuals. As if that's not enough to make us feel really bad about ourselves and our mates, technology now allows photos to be instantly beautified, thereby intensifying the effects of our automatic social comparison mechanisms (Yong et al. 2017).

In yet another line of work on mate preferences, Kenrick and Li solved a paradox in the literature. Evolutionary theorists have argued that physical attractiveness is a cue to female fertility and that a man's social status is a cue to his ability to provide resources critical for offspring survival (e.g., Buss 1989; Symons 1979). Without these traits, reproduction and offspring survival in an ancestral environment are not possible, respectively. Yet, although empirical work shows sex differences in the predicted directions for mate preferences regarding physical attractiveness and social status, numerous mate preference surveys indicate that these traits are not considered to be particularly important. To resolve this paradox, Kenrick and Li introduced a budget allocation methodology to constrain people's selection of traits (Li et al. 2002; Li and Kenrick 2006). When budgets are low and choices are highly constrained, men prioritized physical attractiveness above other traits, and women prioritized social status above other traits for long-term mates. However, when budgets were higher and choices were less constrained, men and women favored other traits. Thus, for long-term mates, men regard physical attractiveness as a necessity, and women regard social status as a necessity. Other traits are considered luxuries – they are important only after necessities can be obtained in sufficient quality.

Dynamical, Complex Systems

Kenrick's foray into dynamical systems reflects his unique ability to see connections at the big-picture level and the courage to go forward with one's convictions. Kenrick uniquely saw how evolutionary psychology, social psychology, and dynamical systems (complexity theory) could be meaningfully combined. At the time, many individuals doubted these ideas. But

Kenrick persisted, and these ideas were endorsed by founders of evolutionary psychology at the 1999 HBES conference and made for a highly cited *Psychological Review* paper (Kenrick's second at this very top journal; Kenrick et al. 2003). The article theorized and demonstrated through simulations that many of the social patterns found at the group level stem from individuals following simple decision rules but interacting with other individuals using the same decision rules. The decision rules are subject to laws of natural selection and process as input the social environment. In turn, the evolved decision rules and how they play out in this space influences the group-level patterns that emerge in the social environment.

Fundamental Motives

In that *Psychological Review* paper (Kenrick et al. 2003), Kenrick identified six major social domains that characterize human life and broadly represent what humans evolved to do: coalition formation, social status, self-protection, mate choice, relationship maintenance, and parental care. Across several papers published with various former students including Joshua Ackerman, Vaughn Becker, Jessica Li, Jon Maner, Jill Sundie, and Vladas Griskevicius, Kenrick examined how activating fundamental motives like mating can influence a host of decisions in seemingly unrelated areas such as conspicuous consumption (Griskevicius et al. 2007; Sundie et al. 2011), conformity (Griskevicius et al. 2006b), creativity (Griskevicius et al. 2006a), economic decisions (Li et al. 2012), facial recognition (Ackerman et al. 2006), interpersonal perception (Maner et al. 2005), and threat perception (Becker et al. 2010). Much of this work is summarized in one of Kenrick's popular books, *The Rational Animal: How Evolution Made Us Smarter Than We Think* (Kenrick and Griskevicius 2013).

More recently, Kenrick took on the ambitious task of rewriting Maslow's hierarchy of needs from an evolutionary perspective (Kenrick et al. 2010). In this highly cited and controversial work, Kenrick replaced the original need levels with

fundamental motives, arguing that parenting, not self-actualization, occupies the very top level.

Conclusion

Douglas Kenrick started out on a path leading nowhere at best and death row at worst. Yet, he went on to become a one of the most influential social psychologists and evolutionary psychologists. On this journey from the gutter to academic stardom, Kenrick has published many important works, leading the world in providing interesting and important big ideas and insights into human behavior and human nature. This entry has covered some of the major areas that Kenrick has examined, but there are many other important papers and topics not mentioned here. Much of Kenrick's work and the surrounding background and inspiration for the work can be found in Kenrick's book *Sex, Murder, and the Meaning of Life* (Kenrick 2011). Just as importantly, Kenrick has induced countless individuals to laugh out loud along the way, whether in papers (e.g., Kenrick 1995), academic talks (e.g., Kenrick 2000) and speaker introductions (Kenrick 1994), or office meetings. At this point, the learned world awaits Kenrick's next big idea as well as his next stand-up routine. In the meantime, readers can tune into Kenrick's insightfully entertaining blog at Psychology Today. Here is one to check out: www.psychologytoday.com/us/blog/sex-murder-and-the-meaning-life/200912/how-the-dawkins-stole-christmas.

Downfall of “Tall Poppies”

Charles Hoogland

Missouri State University, Springfield, MO, USA

Synonyms

Envy; Inferiority; Resentment; Schadenfreude; Status-leveling

Definition

A status-undermining misfortune suffered by another or others of higher relative status, or “tall poppies.”

Introduction

Higher-status people enjoy greater access to high-quality mates and other resources than those of lower status (Buss 1999). Thus, people have evolved to maximize their status relative to competitors, as natural selection favors people with greater reproductive success than others in the local environment (Buss 1999, 2000). One way people of lower status can decrease the status gap between themselves and their rivals is prestige-enhancing skill building – that is, they can “build themselves up.” Another way to accomplish the same status-leveling goal, however, is by promoting status-decreasing misfortunes among one’s rivals, thereby leveling the others down (Buss 1999, 2000; van de Ven et al. 2009; van de Ven et al. 2014). The focus of this entry will be on the latter route to narrowing fitness-jeopardizing status gaps between the self and others – as Buss (1999) noted, “The pleasure people feel in a rival’s misfortunes may act as a motivational mechanism to promote those misfortunes” (p. 367), an idea later supported empirically by social neuroscience research (e.g., Cikara et al. 2011).

“Tall poppies” are high-status people whose outstanding achievements and talents make them stand above the rest of the crowd. Given the crucial role of relative status in determining reproductive success, it is little wonder that literary references to the *downfall* of such tall poppies date to at least the lifetime of the Roman historian Livy, who referenced the story of King Tarquinius decapitating the heads of the tallest poppies in his gardens. That symbolic message was relayed to his son, who proceeded to bring the rebellious state of Gabii to heel by ridding it of its leaders, or tall poppies (Feather 1994). In part as a response to the widespread belief in Australia that Australians particularly enjoy seeing tall poppies fall, Australian social psychologist

Norman Feather (1989, 1994, 2012) pioneered research on people's reactions to tall poppies being cut down to size via a number of different sorts of misfortunes under varied circumstances. This research led to the identification of key determinants of reactions to misfortunes befalling high-status people, such as the perceived deservedness of those misfortunes.

As evolutionary psychological thinking and abundant empirical research across many different cultures suggests, "tall poppy syndrome," or the desire for exceptional, high-status people to suffer misfortunes, is far from a uniquely Australian phenomenon. A common Japanese aphorism, for example, states that "The nail that stands out gets pounded down." Interestingly, Feather and McKee (1993) found that Japanese people expressed a greater tendency toward favoring the downfall of tall poppies than did their Australian counterparts, who tend to have relatively more independent self-construals and thus a greater comfort with those whose outstanding achievements distinguish them from others.

A number of different reactions to the downfall of tall poppies are possible, including feelings of sympathy or pity. This entry, however, will focus on *schadenfreude*, or joy over the misfortune, and primary antecedents of it suggested in the empirical literature. These will include (1) inferiority, (2) hostility, (3) unfairness and deservingness, (4) envy, and (5) perceived gain.

Inferiority

Self-esteem likely evolved as a "sociometer," or indicator of one's social value and chances of social exclusion, which can have negative consequences indeed for one's fitness (Leary et al. 1995). As such, people are exquisitely attuned to signals of their social value, which is reflected in part by their position in the status hierarchy (Smith 2013). Relative inferiority in self-relevant domains is likely to threaten self-esteem and lead to painful feelings of inferiority, especially when the advantaged person is both similar and psychologically close to the disadvantaged person (van Dijk et al. 2011a). That painful

inferiority, however, should motivate status-leveling corrective action, as one's status may be genuinely threatened, and a self-relevant goal (e.g., of status-enhancing professional achievement) has been frustrated by the other's superiority (DelPriore et al. 2012; Floyd et al. *in press*; Frijda 1988; Hill and Buss 2006).

Van Dijk and colleagues (2011b) found that students felt threatened following failure on a self-relevant test of academic ability, priming them for joy over the academic failure of a high-flying, star student. In line with evolutionary theory, however, prior failure (as opposed to success) on the test led to increased *schadenfreude* *even when the domain of the misfortune was unrelated to the domain of relative inferiority*. Both domain-relevant and domain-irrelevant misfortunes can reduce painful status gaps, as status is often based on excellence or superiority in a variety of domains, such as interpersonal popularity, intelligence, athleticism, or physical attractiveness. The downfall leads to happiness because it can help repair threatened self-esteem – one's social value has increased relative to an erstwhile superior, similar other.

In addition to acute self-esteem threat, chronically low self-esteem sets the stage for increased *schadenfreude* when a "taller" poppy suffers a misfortune, although self-affirmations (e.g., reflecting on one's values or important aspects of one's life) can substantially weaken that tendency (van Dijk et al. 2011b). One reason self-affirmations might reduce self-threats (whether acute or chronic, domain-specific or global) is that they may help people convince themselves that their standing is not particularly threatened by relative inferiority to taller poppies, whether or not that perception reflects reality.

Inferiority's effects on *schadenfreude* are not limited to interpersonal situations; inferiority, and indeed other antecedents of *schadenfreude*, such as disliking, deservedness, and resentment, has also been found to operate at an intergroup level (Hoogland et al. 2015; Leach and Spears 2008). For example, in a study of students' reactions to the performance of their university quiz bowl team, Leach and Spears (2008) found that when the students' team was defeated, an emotional

process called *ressentiment* occurred, whereby inferiority feelings were later transmuted into vengeful, hostile feelings toward teams who were not involved in their team's defeat. As a result of *ressentiment*, when a third-party team lost, *schadenfreude* resulted despite that team's having had nothing to do with their team's loss (Leach and Spears 2008). Notably, this suggests the possibility that, at a deeper level, the *schadenfreude* toward the third-party team was driven by a perceived reduction in the status of a possible future competitor and thus a perceived increase in the relative status of the students' own group.

Hostility

Ill-will engenders *schadenfreude* in both intergroup (Hoogland et al., 2015; Leach and Spears 2008) and interpersonal (Feather 1994; Hareli and Weiner 2002) situations. For example, hostile feelings of anger, dislike, and hatred are each other-directed negative emotions that predict *schadenfreude* in reaction to both mild and severe misfortunes suffered by average and superior others alike (Hareli and Weiner 2002; Smith and Kim 2007). That hostility and subsequent *schadenfreude* may or may not be driven by envy (van de Ven et al. 2009, 2014). For example, even during a strong year for a perennially excellent college basketball team, in-group identification-based hatred of a rival basketball team was positively associated with *schadenfreude* following a very severe misfortune – an excruciatingly painful, career-ending injury suffered by a player on the rival team (Hoogland et al., 2015). Given such findings, it may come as no surprise that hostility-based *schadenfreude* is related to both passive and active status-leveling behaviors, including withholding of help (Hareli and Weiner 2002) and negative gossip and interpersonal rejection (Duffy et al. 2012).

Perceived Unfairness

People with poorer relative outcomes often believe them to be unfair, a judgment frequently

coupled with the appraisal that others with superior deserts enjoy them unjustly. Such unfairness judgments can be classified as either objectively or subjectively unfair, although objectively unfair advantages are, by that fact, also subjectively unfair. Objectively undeserved advantages are those that, by social consensus, are considered to be unfair, such as advantages gained by cheating, while subjectively undeserved advantages feel unfair despite being considered fair by most others in one's culture (Smith and Kim 2007). Subjectively unfair advantages include those largely outside of personal control, such as greater intelligence and physical attractiveness, often making them seem unfair to a disadvantaged person despite being "objectively" fair in others' eyes. That is, the perceived controllability of a (dis)advantage often drives subjective fairness judgments (Floyd et al. [in press](#)).

Making a distinction between objectively and subjectively unfair advantages can be useful to understanding and predicting the consequences of such justice-related judgments on *schadenfreude*. When another's advantage is perceived to be objectively and subjectively fair, the resulting reaction is likely to be a hostility-free motivation to move oneself up, and sympathy, not *schadenfreude*, should result if the justly advantaged other suffers a misfortune (van de Ven et al. 2014). Appraising another's advantage as objectively unfair, however, is especially likely to foster resentment, a robust predictor of *schadenfreude*, along with relatively open actions against the person with the unjust advantage, including public expressions of righteous indignation (Feather 2012; Krizan and Smith 2014). Judging that advantage as subjectively unfair, on the other hand, is likely to engender hostility-tinged, malicious envy and more secretive actions aimed at cutting down the unfairly advantaged tall poppy. To openly oppose another's "objectively" fair advantage would risk negative consequences, such as being branded "envious" by others, counterproductively widening the status gap between the self and the *subjectively* unfairly advantaged other. In short, the perceived objective and subjective fairness of a tall poppy's relative advantage partially determine which emotions

and behavioral tendencies follow from that advantage. These include the extent to which schadenfreude and refusing to help, rather than sympathy and helping, will characterize the disadvantaged person's emotions and actions following the downfall of the tall poppy.

Perceiving another's relative advantage as unfair and therefore undeserved (e.g., because he or she did not expend much effort to attain that advantage) enhances schadenfreude and dampens sympathy following the fall of tall poppies, as do judgments of personal responsibility for the misfortune itself (Feather and Sherman 2002; Feather 2012). In fact, the perceived deservedness of both the tall poppy's advantage and the misfortune may be influenced by a multitude of factors, and deservedness perceptions frequently mediate links between schadenfreude and its antecedents, including envy, dislike, and resentment (Feather 2012). Deservedness may therefore play a central role in many, if not most, instances of schadenfreude following the downfall of a tall poppy.

Envy

Despite the intuitive link between envy and schadenfreude, envy's role in reactions to the downfall of tall poppies has been a topic of perennial controversy in the empirical literature, in part because some empirical studies have yielded an association between envy and schadenfreude, while others have not (Hoogland et al. *in press*). The seemingly puzzling null results were likely a consequence of the widely varying ways in which envy has been conceptualized. For example, Smith and Kim (2007, p. 46) defined envy as "An unpleasant, often painful emotion, characterized by feelings of inferiority, hostility, and resentment caused by an awareness of a desired attribute enjoyed by another person or group of persons." When envy includes hostility and resentment, along with a motivation to pull the other down, it is considered "malicious envy," which does predict schadenfreude; however, another type of envy, which occurs equally frequently, is "benign envy," which, though painful, includes no ill-will and instead inspires self-improvement efforts (van

de Ven et al., 2011, 2014). Not surprisingly, benign envy does not predict schadenfreude following advantaged-others' misfortunes – such unpleasant events are not seen as deserved, the advantages themselves are perceived to be fair, and perceptions of personal control over the situation tend to be high, as self-improvement seems possible. Notably, that self-improvement need not be in the domain of perceived relative inferiority, supporting the evolutionary psychological hypothesis that the pain of envy exists to motivate people to improve their relative status, whether via pulling others down (malicious envy) or by building themselves up (benign envy), irrespective of whether such status-leveling actions impact the domain of inferiority itself (DelPriore et al. 2012; Hill and Buss 2006; van de Ven et al. 2009, 2014).

Both advantaged and disadvantaged parties incur envy-related costs in ways tending to maximize their long-term relative outcomes. Tall poppies, for example, are well aware of the possibility that others envy them, and therefore take steps to prevent others from either (1) actively attempting to cut them down to size or (2) failing to provide assistance should they suffer a misfortune. Behaviors aimed at obviating such undesirable outcomes, however, often entail personal costs. They are therefore only performed when perceived as necessary. For instance, fear of malicious envy, but not harmless, benign envy motivates costly prosocial behaviors benefiting lower-status people, thereby reducing their invidious hostility (van de Ven et al. 2010). Just as placating the less fortunate can be costly, *expressing* envy in the hopes of receiving a larger share of a resource can also be costly. For example, envy will be especially pronounced when another possessing an easily shareable resource is nonetheless *not* expected to share it (Inoue et al. 2015). In such instances, the benefits of making envy-driven demands for divisible resources from people otherwise reluctant to share them are relatively likelier to outweigh the costs (e.g., possible reputational damage) than when such demands are either expressed toward (1) someone who already appears inclined to share a divisible resource or (2) someone who simply cannot

share a resource because it is very difficult or impossible to do so (Inoue et al. 2015). In sum, both tall poppies and those looking up to them from below modulate their behaviors to maximize benefits while minimizing costs.

Gain

A final determinant of schadenfreude in response to the downfall of tall poppies is perceived personal or in-group gain. For example, sex-specific differences in joy over the mate-value-reducing misfortunes of potential intrasex competitors suggest that one of schadenfreude's functions may be as a mate-value-tracker (e.g., Colyn and Gordon 2013; see entry ► ["Schadenfreude"](#) for a review). Further, across several studies of reactions to minor and severe misfortunes suffered by an outgroup member, Hoogland and colleagues (2015) found that perceived in-group gain was an even more powerful and consistent mediator of schadenfreude in response to those misfortunes than dislike and resentment of the outgroup. Moreover, when competition and hatred are particularly intense, as is so often the case in political matters, perceived-gain-based schadenfreude may even occur in response to extreme misfortunes. For instance, many highly identified Democrats experienced some degree of schadenfreude when they learned of US troop deaths during the Second Iraq War, as they hoped those tragic losses would lead to Republicans' losing power and, ultimately, an end to the war (Combs et al. 2009).

Conclusion

Factors playing major roles in the degree to which people feel malicious joy or empathic sympathy when tall poppies fall include perceived inferiority to and hostility toward the tall poppy, the perceived unfairness of the tall poppy's advantage, the perceived deservedness of the misfortune itself, envy, and perceived personal gain as a result of the tall poppy's downfall. The operation of these factors, moreover, can be predicted on the

basis of evolutionary psychological theory. Accumulating empirical evidence suggests that schadenfreude is a cross-culturally universal emotion that evolved to motivate adaptive responding when misfortunes befall others, perhaps especially those of higher status.

Drug Sensitization

Androulla Ioannou and Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

Sensitization

Definition

An increase in drug effect upon continual exposure to a drug in the organism, which was previously exposed to the drug.

Introduction

Drug sensitization is a process frequently encountered in the literature of the field of addictions and pharmacology, and it is an essential process towards the understanding of drug action and use.

Drug Sensitization in Substance Abusers

With repeated drug administration, gradual and incremental neuroadaptations are produced that make animals hypersensitive to the specific drugs. Even though users or abusers will be keeping the same dosage levels, drug effects will be greater and greater, therefore they would become intoxicated even in small doses. Using repeatedly a drug but with some pauses in between causes greater sensitization compared to taking a single dosage or even taking repetitively the drug. Moreover, sensitization is promoted if periods of use are alternated with periods of abstinence. When a person who is sensitized let's say to cocaine and abstains from use for some time, he/she is at risk of fatal overdosing at reuse (Steketee & Kalivas 2011;

Robinson & Berridge 2008). Known addictive substances, that sensitization has been observed in, are cocaine, amphetamines, morphine, nicotine, and even alcohol; importantly, not all drugs subject to sensitization, mostly stimulants. In addition, the selected route of drug administration as sensitization is influenced by the speed or the time it takes for a drug to reach the brain. Sensitization in the case of drugs is long lasting with its effects on behavior and cognition lasting for years even with abstinence; however, factors such as the time lapse between dosages, the choice of drug, the age and sex of the user, and genetics influence the strength of sensitization. Due to these factors, vulnerability to sensitization differs between individuals Steketee & Kalivas (2011). That provides an insight into the long-asked question of why some users become addicts while others do not get addicted. The sensitization of behavior and other psychological or psychomotor functions implies neural sensitization. Drugs seem to alter or reorganize neural systems and neurotransmitters, and even though causal relationships are yet to be established, neuroadaptations seem permanent. The permanency of changes in neurotransmitter circuits have crucial implications on the matter of cravings and relapse. Of special importance is the sensitization of the mesolimbic pathway of the mesotelencephalic dopamine system. Since dopamine is responsible for the motivation to go after pleasure and happiness and fulfill our “wants,” drugs come to jeopardize this process by making dopamine hyperreactive, consequently increasing the prominence of drug cues, hence the intense cravings Robinson & Berridge (2008). The aforementioned comprise the “Incentive Sensitization” theory of addiction developed by Berridge and Robinson (1998) and is noteworthy of further reading.

Conclusion

Drug sensitization is a complex process influencing drug users in a cellular level and in consequence in a behavioral level.

Drugs and Rape on College Campuses

George B. Richardson

Substance Abuse Counseling Program, School of Human Services, College of Education, Criminal Justice, and Human Services, University of Cincinnati, Cincinnati, OH, USA

Definition

The association, on and about college campuses, between psychoactive substance use and the use of force or threat of force to achieve penetration of an individual without their consent.

Introduction

The association between alcohol use and rape on college campuses is addressed in ► [“Alcohol and Rape on College Campuses”](#). This brief entry presents an evolutionary perspective on the possible role of other psychoactive substances in rape on and about college campuses, attending to potential interactions between the psychoactive

effects of these drugs and hypothesized rape and rape avoidance adaptations. As reviewed in *Alcohol and Rape on College Campuses*, surveys of college students suggest that among the types of sexual assault, unwanted sexual contact and coercion are most common, followed by incapacitated rape (i.e., completed rape while the victim was intoxicated) and then forcible rape (Fedina et al. 2016). Estimates of the prevalence of sexual assault, including rape, vary widely. Prevalence estimates for incapacitated rape have ranged from 1.8 to 14.2% for females and been observed at 1.9% for males, while forcible rape estimates have ranged from .5 to 8.4% for females and from .6 to .7% for males (Fedina et al. 2016). Fedina et al. (2016) contend that this variance stems from measurement and definitional differences. It is important to note that these estimates rest largely on samples of White, heterosexual, female students in traditional colleges – the prevalence of sexual assault among minority females may be higher and rape incidence is likely underestimated generally due to underreporting.

Drug Use and Rape

High profile cases of drug-assisted rape, along with high profile antispiiking campaigns, might give the impression that rape via spiking (i.e., administration of a psychoactive substance to a person without their consent) is relatively prevalent. However, research on toxicology consistently suggests that there are very few cases in which rape is occasioned by nonvoluntarily consumption of substances (Lovett and Horvath 2009). For instance, analyzing a large sample of suspected drug-assisted rapes, Scott-Ham and Burton (2005) found that 45% of cases involved alcohol, 32% involved illicit substances, and only 2% involved a sedative or disinhibiting substance that could be tied to nonvoluntary consumption. The results of studies across Europe, USA, and Canada indicate that alcohol is the substance that most often occasions sexual assault, running counter to media representations of the psychoactive substance-sexual assault connection (Horvath and Brown 2006; Lovett and Horvath 2009).

Notably, one study of college students in the USA found that only about 13% were aware of this fact (Crawford et al. 2008). Horvath and Brown (2006) raised the question of whether drug-assisted rape is in fact a misnomer – it brings to mind nonvoluntary consumption, but in most cases, drug-assisted rape actually implies self-intoxication through alcohol use and offender targeting of victims on the basis of their alcohol consumption.

Evolution, Drugs, and Rape

As noted in *Alcohol and Rape on College Campuses*, rape has been observed across all human cultures and males in many nonhuman species have evolved strategies to sexually coerce and rape females (McKibbin and Shackelford 2011). As in nonhuman species, human perpetrators of sexual assault are nearly always male and victims are most often female (Testa and Livingston 2009). Many psychoactive substances (e.g., cocaine and marijuana), like alcohol, can be disinhibiting and also sensitize salience through their effects on activity in the prefrontal cortex and dopamine transmission, respectively (George and Koob 2010; Robinson et al. 2013). Thus, the consumption of psychoactive substances other than alcohol may also increase the likelihood that some males will commit sexual assault by modulating brain activity such that cues to the execution of adaptations contributing to rape are amplified (for further discussion of this, see *Alcohol and Rape on College Campuses*). This might occur via effects on the perceived biological value of potential victims, diminished ability to shift attention away from perceived sexual opportunities, reduced capacity for inhibiting sexual arousal, and reduced awareness of the costs that could stem from rape. Also like alcohol, the consumption of other substances could inhibit the execution of rape avoidance adaptations in females (for discussion of female rape avoidance adaptations, see McKibbin and Shackelford 2011), making some females less likely to avoid strange men, avoidant of being alone, aware of their surroundings, and able to resist forcible rape.

Consistent with the possibilities raised above, consumption of drugs other than alcohol is also associated with sexual offending (Kraanen and Emmelkamp 2011) and prospective studies suggest that consumption of drugs such as marijuana also increases the risk for experience of rape (Messman-Moore et al. 2008).

Conclusion

Rape on college campuses has been linked to psychoactive substance use. This brief entry presented an evolutionary perspective on the possible role of drug use in rape on and about college campuses, reviewing evidence suggesting that drugs other than alcohol may similarly contribute to rape through their effects on the brains of would-be male rapists, as well as by interfering with the functioning of rape avoidance adaptations employed by potential female victims. This entry also attended to evidence that rape via spiking is quite rare and thus drug-assisted rape should generally be understood as offender targeting of females self-intoxicated through their consumption of alcohol and/or other drugs.

Definition

Dual Inheritance Theory is a theoretical framework positing that human biology and behavior are influenced by two lines of inherited information: a genetic line, which all species inherit from their biological parents, and a cultural line, unique to our species, which we inherit from other members of our society.

Introduction

Dual Inheritance Theory was first developed by two population geneticists (Cavalli-Sforza and Feldman 1981) and an anthropologist and an ecologist (Boyd and Richerson 1985) as a set of formal mathematical models to describe the transmission and evolution of culture – beliefs, values, behaviors, technology, and other socially transmitted knowledge possessed by societies around the world. Both pairs of scholars drew on the rich toolkit of evolutionary biology that had so nicely described the rest of the natural world, extending it to explain humans as a new kind of animal. The theory identified the conditions that

lead any species to rely on social learning (learning from conspecifics) over individual or asocial learning (figuring things out by oneself); the ways in which social learning could transmit cultural information, copying biological parents (vertical transmission), peers (horizontal transmission), or other members of the parents' generation (oblique transmission); and the biases on what to learn and who to learn from – including payoff biases (e.g., copying successful individuals) and frequency biases (e.g., copying the majority). These models described how culture met the criteria for an independent adaptive evolutionary system: variation, transmission, and selection. Humans, they argued, have two lines of inheritance: (1) a genetic line, which all species inherit from their genetic parents, and (2) a cultural line, unique to humans, which we inherit from our societies. The secret to human success is cumulative cultural evolution – a package of knowledge, know-how, technology, beliefs, and behaviors, adapting and accumulating generation by generation, often outside conscious awareness, and beyond what even the brightest individual could create alone in a single lifetime.

In developing this framework, Cavalli-Sforza and Feldman and Boyd and Richerson expanded evolutionary biology to include the human animal and its social world; offered a formal mathematical toolkit that allowed scientists to develop theories about human behavior, psychology, and society in a manner consistent with the other natural sciences; and laid the foundations for a formal and general “Theory of Human Behavior.” In the following decades, the next generation of researchers expanded the set of models and compiled and created anthropological, archeological, economic, and experimental psychological evidence testing the various formal predictions (Chudek et al. 2015; Henrich 2016; Laland et al. 2010; Mesoudi et al. 2006; Muthukrishna and Henrich 2016).

Theories falling under the Dual Inheritance Theory framework have offered explanations for a wide range of phenomena, from infant cognition, norm psychology, and in-group ethnic biases at an individual level to the source of cross-cultural differences, relationship between

sociality and cultural complexity, and transitions between stable equilibria at a societal level. In an act of self-reflection, recent theories have also tackled the problem of innovation, offering an explanation as to why at least two groups of independent researchers developed Dual Inheritance Theory (Muthukrishna and Henrich 2016). Before discussing these processes, it would help to have some perspective on the history of evolutionary biology and psychology.

History

In 1859, Charles Darwin published *On the Origin of Species* laying out the theory and evidence for evolution by natural selection. The theory was far from universally accepted, and Darwin faced a great deal of hostility, not only from the religious but also from members of the scientific community. In 1864, physicist Lord Kelvin used the rate of cooling to calculate the age of the Earth as no more than 400 million years, an estimate which left insufficient time for evolution by natural selection. Given such opposition, evolution by natural selection did not become a dominant paradigm for some time, particularly in the psychological and behavioral sciences. Wilhelm Wundt, the father of experimental psychology, rejected the evolutionary approach altogether. However, evolution's impact was visible in some schools of early psychology. For example, the relationship of humans to other animals was assumed in George Romanes' work on comparative psychology and William James' search for human instincts.

In 1903, the heat released by radioactive decay was discovered, setting the stage for a revision of Lord Kelvin's calculations by an order of magnitude, leaving enough time for Darwinian evolution. Evolution by natural selection gradually became the bedrock of the biological sciences. The early twentieth century saw the mathematical formalization of evolutionary theory, most notably spearheaded by Ronald A. Fisher, Sewall Wright, and J.B.S. Haldane. During the 1930s, apparent inconsistencies between macroevolution and microevolution, between the rediscovered

discrete Mendelian genetics and both continuous population distributions (e.g., height) and gradual changes, were reconciled, creating a theoretical synthesis across a wide range of subfields of biology: *The Modern Synthesis*.

The Modern Synthesis was a milestone in the biological sciences, but the human and social sciences – including economics, anthropology, and psychology – were missing from this synthesis. As psychology transitioned through the behaviorist and then cognitive revolutions, the biological sciences, with evolution at its core, were largely ignored (with ethology as a notable exception). The psychological sciences had yet to fully incorporate the logic of evolution, biological approaches, and the formal mathematical toolkit.

Evolutionary approaches began to reenter psychology during the 1970s and 1980s. John Bowlby, as part of his work on attachment theory, coined the term *environment of evolutionary adaptedness* (EEA). The EEA referred to the environment to which organisms had adapted. Evolutionary psychologists have since explored in great detail the mismatch between the modern world and the human ancestral environment in Africa (human EEA). Evolutionary approaches also reentered psychology in testing the predictions of evolutionary logic that applied broadly to animals, including humans. For example, the implications of Robert Trivers' *Parental Investment Theory* (1972) was tested by several researchers including Martin Daly and Margo Wilson (Cinderella Effect) and David Buss (sex differences in jealousy). This early work relied on testing predictions from evolutionary biology generated using its standard toolkit. In 1992, anthropologists Jerome Barkow and John Tooby and psychologist Leda Cosmides edited *The Adapted Mind*, laying out additional research and new methodological approaches to identifying further human-specific adaptations to the human EEA.

Earlier attempts to directly expand the modern evolutionary synthesis to the social sciences more generally can be traced to biologist Edward O. Wilson's 1975 book *Sociobiology: The New Synthesis* that brought together a growing body of work to explain the evolutionary processes underlying social behaviors such as

communication, dominance, and altruism. In 1981, Wilson, along with his then postdoc, Charles J. Lumsden, published *Genes, Mind, and Culture*, an attempt to formalize some of the ideas Wilson had laid out in sociobiology as a step toward unifying the biological and social sciences (In a twist of history, Boyd and Richerson applied to spend time in Wilson's lab at around the time Lumsden was a postdoc. Wilson responded that his lab was full and their efforts ended up being independent.). It was in the same year, 1981, that Cavalli-Sforza and Feldman published their classic. In their book, the core tenets of evolution such as mutation, selection, and drift, along with the process of transmission, were used to create formal mathematical models of cultural transmission similar to those used in population biology. These models examined the conditions and factors facilitating cultural transmission and demonstrated its possible forms – namely, vertical transmission from one generation to the next and horizontal transmission between conspecifics. Soon after, in 1985, Boyd and Richerson took a similar approach, once again noting the similarities and differences between cultural transmission and biological transmission. Their research laid out the conditions and implications of biased cultural transmission – the role that learning biases have in the transmission of culture. Perhaps due to the independent disciplines in which they originated, throughout the 1990s, the traditions laid out by Boyd and Richerson and Cavalli-Sforza and Feldman proceeded largely independently from that laid out by Barkow, Tooby, Cosmides, and other evolutionary psychologists.

Dual Inheritance Theory and cultural evolution began to influence psychology through comparative and developmental work from figures such as Andrew Whiten and Michael Tomasello and their collaborators, as well as through the theoretical and experimental work of figures such as Joseph Henrich and Kevin Laland and their collaborators. The key aspects of Dual Inheritance Theory are an evolved psychology that undergirds our capacity for culture, the dynamics of cultural evolution, the selective pressure culture has exerted on our genes (culture-gene coevolution), and cultural-group selection.

Cultural Evolution and the Capacity for Culture

Dual Inheritance Theory is an extension of evolutionary theory (rather than an analogy) into the realm of culture. An adaptive evolutionary system, be it genes or a computer scientist's genetic algorithm, requires three factors: variation, transmission, and selection (Or more generally, variance reduction, such as genetic or cultural drift. While this is still evolution, for evolution to be adaptive, the variance reduction needs to be in an adaptive direction.). Humans have evolved abilities and proclivities that give our cultural system these three properties. Variation is easy – individuals do all kinds of things for all kinds of reasons: mistakes in copying, differential access to information and life experience, blind luck, and so on. The key lies in transmission and selection. The starting point is the tendency to rely on social learning.

In their 1985 classic, Boyd and Richerson laid out the environmental conditions that lead to any species relying on social learning. The answer lies in environmental variability. When the environment is highly stable, genes can adapt well. Consider the average amount of sunlight as a function of latitude. Although there is seasonal variability, as you move North the average amount of sunshine decreases. Rather than relying on culturally acquired information or individual learning, human skin color has genetically adapted to provide the appropriate amount of protection while also providing enough vitamin D through UV exposure. In the modern world of distant migrations, dark-skinned individuals in Northern latitudes generally require vitamin D supplementation, and lighter-skinned individuals in Southern latitudes generally require sunscreen. At the other extreme, when the environment is highly unstable, genes are unlikely to evolve at a rate fast enough to match the environmental change. In such unstable environments, genes for individual learning are favored, since the long-term past is not a good predictor of the future. Between these extremes is a Goldilocks zone where your parents and grandparents have knowledge worth paying attention to. As an example, consider a cyclical

drought. You may never have experienced a drought, but your parents and grandparents remember the last time there was a drought and where the village found water and what else they did to survive. In this Goldilocks zone of intermediate environmental variability, social learning is favored. These predictions were formally modeled in 1985, but the data to test this theory didn't emerge till ice core data was made available in the next two decades. The data fit nicely – climate variability increased around 3 million years ago, just as the *Homo* genus emerged. Of course, this argument predicts widespread social learning (which is what we observe; Hoppitt and Laland 2013). Social learning alone is not sufficient.

One form of social learning is imitation: humans tend to copy with *high fidelity*, often with an absent or incomplete causal model. An experiment by Victoria Horner and Andrew Whiten (2005) nicely illustrates this proclivity. Chimpanzees and human children were presented with two versions of a puzzle box with a reward inside. The experimenter presented a series of causal and irrelevant actions to access the box. When the box was opaque such that both chimpanzees and children couldn't distinguish between the causal and irrelevant actions, both imitated all experimenter actions. But when the box was transparent and the irrelevant and causal actions were easily distinguishable, the chimpanzees only copied the causally relevant actions. The children, in contrast, continued to copy all actions. More recent evidence suggests that children can distinguish between instrumental behaviors where all that matters is the outcome and conventional behaviors that are either normative or where a causal model isn't apparent. However, life is mostly made up of a world too complex to fully understand, and understanding is often not required – from cooking by copying family recipes without the need to understand the underlying biochemistry to using a computer without the need to understand the computer science and physics which drive it. Research by Herrmann et al. (2007) further illustrates the abilities and proclivities that underlie the capacity for culture through cognitive tests with human children,

chimpanzees, and orangutans. In the physical domain of space, quantiles, and causality, humans were no better than the other primates. But in the social domains of Theory of Mind, communication, and most clearly social learning, they thoroughly outcompeted their primate cousins.

Humans are highly reliant on high-fidelity social learning, but we don't copy arbitrarily; we learn selectively from successful, self-relevant and reliable sources of information. Much theoretical and experimental research in cultural evolution has identified a constellation of strategies and biases through which we acquire information. For example, we tend to copy experts with greater skill, those who are generally successful, and those who others are paying attention to (prestige). When these payoff biases exist, over time, the population acquires a package of the most adaptive beliefs and behaviors, so we also copy majorities and pay attention to changing frequencies (trends) in the population. Not all information is equally relevant; sometimes someone is a better model for you. We moderate these selective biases on self-similarity, such as sex and ethnicity. Children will often copy children only slightly older than themselves, since they provide behaviors more relevant to their personal ecology. Since not all sources of information are equally sincere, we also seek out costly and credibility-enhancing displays (CREDs) that increase our trust in the information. And because not all domains are equally important, we focus on certain content over others, such as dangers, mating-relevant information, reputational information and norms (Chudek et al. 2015).

The world in which we now find ourselves is more complex than any one of us can understand or recreate. Culture adapts to the local environment, including to aspects of the environment that are genetic. For example, our species gives birth to large-brained, helpless infants that require extra care. There are many cultural solutions to this core problem, from controlling female sexual access and forcing fathers to look after their children to the fatherless societies where brothers are expected to look after their sisters' children to societies with multiple fathers and corresponding partible paternity beliefs (Henrich 2016;

Muthukrishna and Henrich 2016). Similarly, genes will adapt to features of the environment that are highly stable, sometimes over short periods. Many of these features to which genes adapt are part of the cultural environment, leading to culture-gene coevolution.

Culture-Gene Coevolution

The classic case of genes adapting to cultural practices is lactase persistence, the uniquely human ability to process lactose beyond infancy. Drinking milk in infancy is a typical mammalian trait, but the ability to process lactose in adulthood is a uniquely human ability but found in less than a third of humans. The domestication of animals, a cultural practice, provided the selection pressure for such variation – milk is a rich source of calories and nutrients, and the ability to process it is highly advantageous, offering an evolutionary advantage to members of a society who could process it beyond childhood. Lactase persistence nicely tracks the domestication and herding of livestock. In an exception that proves the rule, lower levels of lactase persistence are present in populations that turned milk into lower-lactose products, such as cheese and yogurt, using culturally evolved milk-processing technologies. Other examples of culture-gene coevolution include processing of alcohol and other food types, and immunity and pathogen defense. Other human features, including language and our social learning abilities and proclivities, may also have been products of culture-gene coevolution adapting to ever-increasing levels of information (Laland et al. 2010).

Cultural-Group Selection

Cultural-group selection is one of the most misunderstood aspects of Dual Inheritance Theory (Richerson et al. 2016). The main sources of misunderstanding are perhaps the problems associated with genetic-group selection, what people think is being selected, and conflation between equivalence of mathematical accounting systems and causal processes.

Genetic-group selection is the idea that natural selection might act at the level of the group as well as at the level of the individual. Group selection would allow for behaviors that were good for the group at the expense of the individual. While in theory group selection might be possible, one key problem is that genetic groups often struggle to maintain their genetic boundaries, such that in the long run, even small amounts of migration (from, e.g., individuals with genes that favor themselves over the group) will eventually make interacting groups genetically similar. Such migration destroys between group differences, and without sufficient variance between groups relative to the variance within groups, intergroup competition can't select between genetic groups.

Some researchers have proposed that cultural-group selection can overcome this problem. Cultural-group selection as a force can be considered a consequence of various aspects of our cultural psychology, most notably our ethnic and norm psychology. That is, our ability to identify the cultural groups to which we belong and to assimilate new members, and our capacity to represent norms and tendency punish violators. We know which groups we belong to and the norms associated with belonging to those groups. As long as migrants are assimilated into the group norms (e.g., immigrants following the laws of their new country or newcomers speaking the group language), group boundaries are maintained. Cultural groups with packages of norms that cause the groups to grow and outcompete neighboring groups can be favored by selection. Empirical research supports the idea that cultural groups can maintain their boundaries. For example, at a country level, cultural differences between neighboring countries far outweigh genetic differences. Similarly, at small-scale societal level, neighboring groups of hunter-gatherers have larger between-cultural-group variance relative to within-cultural-group variance. These group differences allow for selection between cultural groups. This leads to the second misunderstanding of what is under selection.

Cultural-group selection refers to selection among cultural groups (rather than a cultural variety of standard "group selection") – that is,

differences in traits between cultural groups may give one group, and the members therein, a selective advantage over a competing group. But what is a cultural group? In the anthropological literature, the cultural group is often defined as the ethnolinguistic group, individuals with a shared cultural history who speak the same language. While this is a strict cultural group, humans belong to multiple embedded and overlapping groups. We can talk about differences between East Asian and Western culture, but equally between Chinese and Japanese culture, or rural and urban regions within China and so on. Similarly, we can belong to overlapping groups such as Boston Catholics and Belfast Catholics. What is really being tracked in a mathematical model and what defines the group are a package of cultural traits – the norms, values, beliefs, and behaviors of the group. That is, cultural groups can be thought of as groups of cultural traits possessed by clusters of people; it's important to distinguish between the cultural traits and the population. Since cultural-group selection is often used to help explain the extraordinary levels of human altruism – groups made up of altruistic individuals would outcompete groups made up of selfish individuals – the cultural traits that often define the cultural group of interest are altruism norms and behavior. But depending on the question of interest, many cultural traits or packages of traits may constitute the cultural group. There are mechanisms and combinations of mechanisms for competition between groups of cultural traits, for example, direct competition, such as warfare between groups; demographic swamping, whereby one set of traits grows at the expense of another; migration, whereby individuals move between groups bringing with them traits that match the new group (assortative migration) or taking on the traits of their new group (assimilation); and prestige-biased cultural-group selection, whereby entire groups of people take on the attributes of a more prestigious group (such as the spread of democracy).

The final misunderstanding lies in the equivalence of the mathematical models of group selection compared to inclusive fitness or individual fitness. These approaches are simply different, but

mathematically equivalent approaches to partitioning the variance when modeling the evolutionary process. Which accounting system makes the most sense (in terms of making it easy to model and understand the selection process) depends on the degree to which the differences between groups contribute to the evolutionary process. The mathematical equivalence does not mean that the causal processes are equivalent, but especially in modeling cultural-group selection, a group selection framework is often the most useful.

Conclusion

Dual Inheritance Theory is an extension of evolutionary biology into the human realm of culture and society. By making precise formal predictions about human physiology, anatomy, and psychology, it offers a potential “Theory of Human Behavior.” And in using the toolkit of the biological sciences, it allows us to synthesize the psychological and social sciences with the biological sciences. It is no surprise then that the models of Dual Inheritance Theory, particularly those associated with social learning, have proven useful in biology and in understanding social learning in other animals. As a theoretical framework, it may do to the psychological and social sciences what the periodic table did to chemistry and what natural selection did to biology. Offer a lens through which thus far disparate empirical findings suddenly make sense.

Dual-Mating Hypothesis

Yanna Weisberg¹ and John Kim²

¹Linfield College, McMinnville, OR, USA

²Lesley University, Cambridge, MA, USA

Definition

The **dual-mating hypothesis** is an important guiding perspective in evolutionary psychology that posits how women may have evolved to develop two overlapping strategies when choosing mates: (A) a short-term strategy that prioritizes men who are high in physical attractiveness and therefore possess “good genes” and (B) a long-term strategy that prioritizes men who are more likely to invest resources in potential offspring (Gangestad and Thornhill 1998; Pillsworth et al. 2004).

Introduction

These strategies are often at odds with each other, as the potential mate who possesses the highest-quality genes is often not the same potential mate who is most likely to invest resources in potential offspring. From the dual-mating hypothesis, researchers have highlighted how women who are faced with this trade-off manage their strategies accordingly, i.e., when they are likely to prioritize genetic fitness versus resource provision from their partners.

Short-Term or Long-Term Strategies?

According to the logic of adaptiveness, both mate-choice strategies (i.e., the preference for good genes in the short term and potential investment in the long term) should be in service of maximizing the likelihood of survival of future offspring (Cosmides and Tooby 1994). Potential offspring are more likely to survive if they have “good genes” that allow them to be resilient to

environmental stressors, as well as caregivers who are willing to invest resources (e.g., time, money, etc.) in ensuring their survival.

However, parental investment theory (Trivers 1972) indicates that men and women should have differing concerns when it comes to mate choice. According to parental investment principles, there are fundamental differences between men and women in mating behavior, due largely to differential parental investment in offspring. For humans in particular, initial female parental investment is much greater than initial male parental investment, given how women and men reproduce. Human gestation occurs within the woman, and a woman typically releases only one ovum per month for a limited period of her life. As a result, it is more costly for women to choose unworthy mates, given the costs of spending 9 months gestating that otherwise could have been spent pursuing better mates. Men, on the other hand, have billions of sperm cells that are viable across their lifespans, and they do not gestate. From an evolutionary perspective, men suffer fewer consequences from an unwise choice of mates.

One implication of this reality is that women tend to be more oriented toward long-term mating strategies, whereas men tend to be more inclined toward short-term mating strategies (Buss and Schmitt 1993). Women should be more discriminating when choosing mates, and they should tend to prefer mates who are more inclined to provide for their offspring, even if they must sacrifice genetic fitness as a result. On the other hand, men should be relatively less choosy when selecting mates, especially short-term mates, and can focus primarily on genetic fitness without worrying about implications for long-term investment.

Famously, Buss (1989) examined the mate preferences of individuals in 37 different cultures (ranging from the United States to Zambia) and found cross-cultural evidence for this sex difference in mate-choice strategies. Men, relative to women, were more attracted to markers of health and fertility (e.g., physical attractiveness), attributes that are not highly correlated with

investment of parental effort. In contrast, because they invest relatively more in each offspring, women were more attracted to markers of a man's ability and willingness to provide resources (e.g., financial wealth and social status). A rich body of literature has further established this relative sex difference in mate-choice strategies, in which men are more inclined toward short-term mating and thus mindful of immediate reproduction goals, whereas women are more inclined toward long-term mating and thus mindful of long-term reproduction goals (e.g., Perilloux et al. 2012).

However, researchers who have adopted the dual-mating framework argue that it is overly simplistic to argue that women universally adopt a long-term mate-choice strategy (Pillsworth et al. 2004). Consistent with the modularity assumption, i.e., that human beings have developed domain-specific evolved mechanisms to solve different problems of adaptation (Barrett and Kurzban 2006; Tooby and Cosmides 1992), it is believed that women prioritize both short-term and long-term mate-choice strategies, with the situational context influencing which strategy is relevant at any particular time. This is somewhat at odds with the idea that the ideal mate-choice strategy for women is to sacrifice good genes in favor of the likelihood of investment. Instead, under this logic, the ideal mate-choice strategy for women should be to choose a long-term partner who is willing to invest in offspring while simultaneously (and perhaps secretly) obtaining good genes via sexual intercourse with a short-term mate (Pillsworth et al. 2004). It is usually impractical to obtain good genes from a short-term sexual encounter while finding a cuckolded partner to invest in the offspring after the fact. In most cultures, there are usually strong social norms that encourage strict monogamy and discourage infidelity (e.g., Conley et al. 2013). Moreover, from an evolutionary perspective, men should be motivated to reduce paternity uncertainty as much as possible, meaning that they will be highly attuned to the threat of sexual infidelity (Buss et al. 1992) and engage in mate-guarding behavior when the threat of infidelity is especially salient (Buss 2002). Nonetheless,

although external pressures may prevent women from enacting this strategy, this still allows for the possibility that women will exhibit a short-term preference for good genes given the right environmental cues.

Trade-Offs Between Strategies

Women could theoretically find a partner who will both transmit good genes and be likely to invest in resultant offspring, but this is difficult to accomplish in reality due to the unavoidable fact that time and energy are limited resources. Gangestad and Simpson (2000) emphasized the importance of trade-offs, i.e., that any adaptation is necessarily going to come with an "opportunity cost" because effort allocated to one adaptive domain could have been allocated to another adaptive domain instead (see also Kaplan and Gangestad 2005). Specifically, they used the example of mating effort versus parenting effort, by highlighting how time and energy devoted to parenting is time and energy that is no longer available to seek out sexual encounters with other potential mates. In regard to the dual-mating hypothesis, this explains why men who have the highest-quality genes are unlikely to be the same men who are most likely to invest in offspring. Likely due to their value as short-term mates, physically attractive men (i.e., men with markers of good genes) have more lifetime sexual partners and are more likely to engage in non-monogamous behavior (e.g., Frederick and Haselton 2007). However, this focus on mating effort means that they may not have the remaining time and energy to put into parenting as a result. Conversely, because less physically attractive men have relatively fewer opportunities to engage in mating effort, they may invest that time and energy into parenting instead, thus increasing their value as long-term mates (Gangestad and Simpson 2000). Moreover, less physically attractive men may be more likely to invest effort in building status and/or wealth in order to further signal their ability to invest in offspring (Kaplan and Gangestad 2005).

Research indicates that women have different criteria for mates depending on if they are asked

to think about short-term or long-term mating concerns. Consistently, researchers have found that women are more likely to use physical attractiveness as a criterion for judging short-term partners and potential extra-pair mates (e.g., Buss and Schmitt 1993; Scheib 2001). Specifically, Frederick and Haselton (2007) found that women perceived muscular men (relative to non-muscular men) as being sexier and more attractive as short-term mates but also less likely to be committed to a romantic relationship, meaning that women are sensitive to the trade-off that men must make between mating effort and parenting effort. Furthermore, Roney et al. (2006) collected measures of both testosterone levels and implicit attitudes toward infants from a sample of men and then asked women to explicitly rate them from their photographs on their attractiveness (A) “as a short-term romantic partner (e.g., for a brief affair)” and (B) “as a long-term romantic partner (e.g., for a committed relationship such as marriage).” In fact, attractiveness as a short-term mate was predicted by testosterone levels (i.e., a marker of good genes), while attractiveness as a long-term mate was predicted by positive implicit attitudes toward infants (i.e., a marker of interest in parenting).

Ovulation and the Dual-Mating Hypothesis

The most compelling evidence for the dual-mating hypothesis comes from research on the ovulatory shift, which is the phenomenon where women show increased attraction toward mates who demonstrate markers of “good genes” (i.e., high physical attractiveness) when they are ovulating and thus at peak fertility (Gangestad and Haselton 2015; Gangestad et al. 2002). In one of the earliest and most noteworthy studies on the ovulatory shift, Gangestad and Thornhill (1998) had female participants smell clothing worn by men of varying fluctuating asymmetries (i.e., a marker of physical attractiveness and good genes) and then indicate their attraction toward the men based only on scent. Despite not actually knowing the fluctuating

asymmetry of the men in question, high-fertility women were more attracted to scents from men who were lower in fluctuating asymmetry, while fluctuating asymmetry had no significant influence on the olfactory preferences of low-fertility women. Therefore, this provided an initial sign that, even if women generally show a preference for long-term mates, they may temporarily shift to a short-term strategy when obtaining good genes is more of a priority (i.e., when conception through sexual intercourse is especially likely).

A plethora of literature has replicated the basic finding that women show an increased cognitive preference for markers of good genes when they are ovulating, but not necessarily markers of long-term investment (see Gildersleeve et al. 2014, for a review). Moreover, it has been shown in multiple studies that women during high fertility are more likely to engage in behavior that should theoretically be more effective in attracting a short-term partner with good genes. For example, ovulating women are more likely to pay attention to physically attractive men (Anderson et al. 2010), express increased interest in attending events where men are likely to be present (Haselton and Gangestad 2006), are more likely to wear clothing that is seductive in nature (Beall and Tracy 2013; Durante et al. 2008), behave more flirtatiously in the presence of available partners (Cantú et al. 2014), and are even more likely to consider infidelity if they are currently in a romantic relationship (Gangestad et al. 2002). In an especially illuminative study, ovulating women in romantic relationships were more critical of their partners when their partners were perceived as sexually undesirable, but felt closer to their partners when their partners were perceived as more sexually desirable (Larson et al. 2013). However, ovulation status did not predict actual commitment to the relationship, providing support for the dual-mating hypothesis by showing that commitment to a partner could be buttressed by both short-term and long-term mate value. Correspondingly, men appear to be sensitive to the ovulatory shift and more likely to engage in mate-guarding behavior when their romantic partners are ovulating (e.g., Fales et al. 2014), providing indirect evidence for the

dual-mating hypothesis by demonstrating that men are perhaps aware of how women are adjusting their mate-choice strategies depending on their ovulatory status.

Conclusion

There have been notable challenges to the dual-mating hypothesis. For example, Buss and Shackelford (2008) pointed out that cuckoldry of a long-term mate, i.e., the ideal mate-choice strategy according to the dual-mating hypothesis, is actually a relatively rare phenomenon (see also Thompson and Muller 2016). As such, they argue that the dual-mating framework is fundamentally flawed and that human females have likely evolved to find the best combination of short-term and long-term mate value in a single partner, rather than attempting to find different partners to maximize each domain. Although researchers using the dual-mating framework already acknowledge that cuckoldry is a difficult mate-choice strategy in practice, Buss and Shackelford (2008) argue that such a strategy is so impractical for most women that it calls into question the extent to which it can really be considered the ideal strategy at all. From this logic, when extra-pair mating actually does occur, it may be better explained by the mate-switching hypothesis, in which women are exploring the possibility of taking on a new partner with greater overall mate value, rather than attempting to maintain relationships with two partners at once (Buss et al. 2017).

Furthermore, although the most compelling evidence in support of the dual-mating hypothesis comes from research on the ovulatory shift, researchers have debated the robustness of these effects, with meta-analyses by Gildersleeve et al. (2014) and Wood et al. (2014) resulting in differing conclusions. However, the body of research on the ovulatory shift as a whole is additional evidence that the narrative of women valuing investment over good genes may be overly simplistic. Future research on the dual-mating hypothesis will likely focus on establishing the robustness of ovulatory effects (Gildersleeve

et al. 2014; Harris et al. 2014; Wood and Carden 2014) as well as determining the particular women for whom and situational contexts in which the dual-mating strategy is especially likely (Buss and Shackelford 2008; Scelza 2013).

Introduction

Contemporary studies reveal widespread global variation in breastfeeding patterns, providing a fascinating example of human behavioral flexibility (Sellen 2009). However, human infant behavior and physiology evolved under environmental conditions that differ notably from those in which most humans live today. Current evidence places the origin of *Homo sapiens* at ~200,000 years ago (Conroy and Pontzer 2012). Ancestral *Homo sapiens* were hunter-gatherers for most of the species' existence until agriculture, urbanization, and industrialization emerged—all within the past ~11,000 years (Ellis et al. 2013). Under ancestral conditions of hunting, gathering, and high infant mortality, infant survival depended on the immunological, hormonal, and nutritional factors in maternal breastmilk (Hinde and Milligan 2011; Volk 2009).

Prolonged breastfeeding is the norm in most contemporary hunter-gatherer populations, and biological patterns of infant digestive and masticatory development similarly suggest that this pattern is also the human ancestral norm (Sellen 2009). Mean age of introduction of solid foods and total breastfeeding durations were 5.0 ± 4.0 months and 29.0 ± 10.0 months, respectively, in an analysis of 113 nonindustrialized populations; cultural groups with “extractive” (hunter-gatherer) economies had longer overall breastfeeding durations than pastoralists and agriculturalists (Sellen and Smay 2001). In stark contrast, breastfeeding rates are low and durations short in many contemporary, industrialized settings, perhaps because technology and medicine minimize selective pressures that have shaped infant biology throughout human evolutionary history (Ball 2008; McKenna and McDade 2005). Life history theory, a branch of evolutionary ecology, provides a useful framework for analyzing population differences in breastfeeding durations, and for inferring breastfeeding patterns throughout human evolutionary history.

Theoretical Approach

Life history theory (LHT) posits that the behavior and life schedules of organisms are shaped by natural selection to maximize biological “fitness” or reproductive success – usually defined by proxy as “the surviving number of offspring of an individual” (Wilson 1975). Biological fitness maximization occurs when energetic resources are optimally allocated to competing life history functions (brain and body growth, survival/maintenance, and reproduction) (Smith and Fretwell 1974; Charnov and Berrigan 1993; Charnov 2004). Organisms have fixed energy budgets, so energetic “trade-offs” occur between competing life history functions (e.g., upregulated survival effort diminishes growth effort) (Stearns 1989) and are most pronounced under conditions of resource scarcity (Tschirren and Richner 2006).

According to LHT, many parenting behaviors are shaped by natural selection. Parental investment is defined as “resource allocation to one

offspring that diminishes a parent's ability to invest in another" (Trivers 1972). In mammalian mating systems, females bear the energetic burdens of gestation and lactation; in most human societies, mothers are higher investing than fathers and provide the majority of offspring care (Konner 2005). Lactation represents a particularly energetically costly form of maternal investment, and as such it "trades off" with other maternal life history functions (e.g., time and energy for self-maintenance, production of food resources, care of other existing offspring, and production of additional offspring) (Prentice et al. 1996). Weaning (the gradual cessation of breastfeeding) can therefore become a source of conflict between mothers and infants (Trivers 1974).

Maternal–Offspring Conflict

Weaning conflict exists due to asymmetry in genetic relatedness between mothers and offspring (Trivers 1974). Mothers are entirely related to themselves, and equally related (by ~50%) to each of their different offspring. Infants are entirely related to themselves, but share fewer common genes with their mothers, and any existing or future (nonidentical twin) siblings. Mothers must therefore partition investment optimally between multiple (current and future) offspring, and between self-maintenance and reproductive effort, to efficiently maximize individual lifetime reproductive success (Lee 1996). However, in accordance with Hamilton's rule, offspring should prioritize their individual fitness over that of their kin; weanlings may adopt behavioral tactics to continue to extract maternal resources (e.g., breastmilk) (Hamilton 1964; Trivers 1974). Common behaviors include smiling, nuzzling, begging, crying, and tantrums, with weanlings sometimes demanding more than mothers are willing to provide (Haig 2014; Trivers 1974). Continued suckling is associated with maternal lactational amenorrhea (postpartum anovulation), which improves weanling fitness by delaying conception and birth of a younger sibling (Haig 2014). Compelling new research suggests that maternal physiology may, in turn, be evolved to modify offspring behavior; for example,

"bioactive components in maternal milk may be influencing the infant microbiota to shift the infant phenotype toward the mother's optima for investment" (Allen-Blevins et al. 2015, p. 117).

Phylogenetic Context of Human Infancy

Life history theory is also used to make phylogenetic comparisons across animal taxa (Charnov and Berrigan 1993; Lee 1996). Several distinguishing human life history traits (slow fetal growth, infant altriciality, short infancy durations, prolonged juvenility, and high fertility) likely evolved in the past ~2 million years, in conjunction with rapid increases in human brain size (Bogin 1998). The human fetus grows somewhat slowly in utero compared to fetal growth in other ape species; humans are born with ~30% of their adult brain size (compared to ~40% for chimpanzees), and human newborns are neurologically altricial compared to other newborn primates (DeSilva and Lesnik 2006). Human infancy – defined here as the period of maternal lactational provisioning – is also fairly short (~1–3 years) in comparison to other great apes (~3–8 years) (Kennedy 2005; Lee 1996). In contrast, human childhood and juvenility are prolonged in comparison to other apes (Bogin 1998).

In nonhuman primates, the end of infancy is marked by the eruption of first permanent molars; in humans, weaning occurs roughly 3–5 years the first permanent molars erupt (Smith and Tompkins 1995). In concordance with a broader pattern characteristic of mammalian species where mothers birth altricial, singleton infants, human weaning tends to be a protracted process in most nonindustrialized populations (Whitehead 1995; Sellen 2009). Notably, in most human societies, nonmaternal group members (fathers, grandparents, siblings, extended kin) assist with provisioning of recently weaned children (Kramer 2010). This practice accelerates the resumption of maternal ovulation post birth, shortens human interbirth intervals relative to other great apes, and facilitates high fertility rates that have come to characterize the human life course (Humphrey 2010).

Breastfeeding and the Weaning Process

Human infants are born immunologically naïve and face pronounced growth–maintenance trade-offs in the first years of life (McDade 2005). Human breastmilk contains nutritional, immunological, and hormonal components that meet the complex demands of developing infants (Hinde and Milligan 2011). Breastfed infants experience lower rates of diarrheal and respiratory morbidity compared to non-breastfed infants, which is especially important in low-income settings where sanitation and medical care access are inadequate (Kramer and Kakuma 2012). Due to these and many other benefits, the World Health Organization (WHO) recommends 6 months of exclusive breastfeeding, and partial breastfeeding for 2 or more years (WHO 2011). The term “weaning” is often used to refer to the complete cessation of breastfeeding but has also been defined as a “more or less gradual process by which milk is first supplemented, and then replaced, by other foods” (Haig 2010). The entire human weaning transition may be broken down into the following three stages:

1. *Exclusive breastfeeding*: The period in which infant nutritional and immunological needs are met exclusively through consumption of mother’s milk. The relative benefits of breastfeeding decline as infants approach 6 months of age, because maternal milk output is limited and infant energetic requirements increase continuously (McDade and Worthman 1998). Although exclusive breastfeeding is not practiced in some settings (in lieu of formula and other breastmilk substitutes), it is essential to infant survival in most past and present socio-ecological contexts.
2. *Partial breastfeeding*: This stage is marked by the introduction of liquid and solid weaning foods that are regularly consumed by infants in conjunction with breast milk. Because increased gastrointestinal infection is associated with the introduction of infant foods, they may be specially prepared to facilitate digestion and minimize antigen exposure (Fouts et al. 2005). Throughout this protracted weaning process,

nonmaternal group members often support young children through nutritional provisioning of processed weaning foods (Humphrey 2010). Partial feeding may last until a child is two or older in nonindustrialized populations (Sellen and Smay 2001). In contrast, initial infant food provisioning is often synonymous with cessation of breastfeeding in some very modernized contexts (Whitehead 1995).

3. *Nutritional independence*: In most mammals, by the onset of nutritional independence (end of the weaning transition) offspring have attained sufficient physical maturity and competence to undertake independent traveling, foraging, food processing, and digestion (Lee 1996). Because human weanlings are not capable of successful independent foraging, they continue to receive foods provisioned by mothers, other kin, and unrelated alloparents (Bogin 1998; Kramer 2010). Provisioned post-weaning foods tend to be energy dense, and provide nutrients required to fuel children’s brain growth, which continues up to 7 years of age and beyond (Kennedy 2005).

Threshold Model of Weaning

Phylogenetic life history comparisons reveal positive correlations between adult and neonatal body weight, adult and neonate brain weight, and interbirth intervals (a proxy for weaning age) (Harvey and Clutton-Brock 1985; Lee 1996). In large-bodied mammals, offspring are typically weaned by a maximum “threshold” body size, which is achieved when the infant grows to roughly quadruple their birth weight (Lee 1996). According to this model, a human neonate born at 3.3 kg will be weaned at 13.2 kg (10.6–16.2), which “corresponds to an age of 2.5 years (1.3–3.9) for breastfed male babies on the 50th growth centile” (Humphrey 2010). Weaning is often thought to occur at this threshold because infant energetic requirements come to exceed the upper limits of maternal metabolic capacity (Lee 1996). It has also been suggested that slow infant growth leads to longer breastfeeding durations in nutritionally and epidemiologically risky

environments (Hochberg 2011). In general, infant growth rates are rapid in the early postnatal phase, decelerate across infancy, and then abruptly accelerate at the onset of the biologically salient transition into childhood. In hunter-gatherer populations, this transition occurs near the mean weaning age (2–3 years) whereas in affluent Westernized countries, it occurs at ~6–12 months (Hochberg 2011).

Facultative Model of Weaning

The “shifting weaning optima” model states that weaning age is facultative and occurs when the maternal costs of prolonged lactation outweigh the infant benefits (Sellen and Smay 2001). A conceptually similar “evolutionary trade-offs” model was proposed by Tully and Ball (2013), more explicitly incorporating Trivers’ (1974) model of parent–offspring conflict. According to these models, prolonged breastfeeding will persist in settings where its benefits to infants are high (e.g., environments of high infectious disease morbidity) and/or when actual and/or perceived maternal time, energy, social, and opportunity costs are low (McDade and Worthman 1998; Tully and Ball 2013; Veile and Kramer 2017). Support for a “shifting weaning optima” has been at least partly supported through qualitative assessments of costs and benefits of breastfeeding in different environments (Veile and Kramer 2017), though it should be noted that the costs and benefits of breastfeeding are challenging to operationalize.

Conclusion

The duration of breastfeeding in human ancestral environments can be inferred through investigations of ancient human fossil remains, extant and extinct nonhuman primates, and contemporary hunter-gatherer populations. Human breastfeeding durations are simultaneously shaped by divergent mother–infant fitness interests, local ecologies, and cultural norms. Despite substantial intraspecific variability in breastfeeding patterns,

combined bodies of evidence suggest that breastfeeding for 2 or more years is the human ancestral norm (Sellen 2009). Though the biological fitness costs of not breastfeeding are reduced in many contemporary modernized settings, prolonged breastfeeding is still an economical, nutritional, and hygienic strategy for maximizing infant survival in many parts of the world.

Developmental stage; Immaturity

Introduction

The period of immaturity is known to be more protracted in humans than in other primates.

This text sets out to compare the various developmental stages of the immaturity period in mammals in order to more specifically explore the adaptive value of each stage for human beings, with special emphasis on childhood.

The Four Stages of the Immaturity Period in Human Beings

Most mammal species progress from infancy to adulthood without any intervening stages (Bogin 1990). The infancy stage ends when breastfeeding stops (Bogin 1997). Highly social mammals, such as wolves, wild dogs, lions, elephants, and the primates, delay puberty with a period of juvenile growth between infancy and adulthood (Bogin 1997). Juveniles are defined as “prepubertal individuals that are no longer dependent on their parents for survival” (Pereira and Altmann 1985). Presumably, adolescence later emerged, by natural selection, among the apes. Adolescence is a period of rapid and profound physical, hormonal, and behavioral change leading up to the full reproductive and social maturity characterizing the adult years (Kraemer et al. 1982). In chimpanzees, adolescence begins at approximately 8 years of age and ends around age 14 for females and 15 for males (Pusey 1990) whereas in human beings, adolescence spans ages 10–18 for girls and 12–21 for boys. Puberty begins in chimpanzee males with significant testicular growth and ejaculation, and in chimpanzee females, with slight swelling during ovulation (Pusey 1990). Human puberty begins with the appearance of the secondary sexual characteristics, then the development of breasts in girls, the enlargement of the testes (less than in chimpanzees) and penis (more than in chimpanzees) in boys, and the onset of interest and activity in adult patterns of sociosexual behavior. Moreover, human adolescence also involves a growth spurt of skeletal and muscular tissue that produces sexual dimorphism in size and physical strength in favor of males, to a greater extent than in chimpanzees. These differences in sexual dimorphism between humans and chimpanzees can be explained by the species’ contrasting

reproduction types. In chimpanzees, intermale competition for access to females is mainly spermatic because of the species’ sexual promiscuity: although the dominant male has a greater likelihood of copulating first, females have sexual relations with many partners. In humans, males are in greater direct competition with one another for access to females within a system of reproduction that features a mix of union types. Although polygynous marriages can be found in most human societies, monogamy remains predominant across the globe given that, in most polygynous societies, only a small portion of men have more than one wife (Chapais 2008).

Given the absence of growth spurts in non-human primates, Bogin (1997, 2011) considers adolescence to be a developmental stage specific to humans. However, this sole criterion seems insufficient, in our view, to deny the existence of adolescence in other animals. Indeed, chimpanzees, too, display an adolescent growth spurt, albeit only in individuals who exhibited delayed growth in the juvenile period as a result of severe environmental pressure (Hamada and Udono 2002). Moreover, the above-mentioned differences between the two species, in terms of sexual organs and sexual dimorphism, should also be taken into account.

According to Bogin (1997), human physical growth from 3 to 7 years of age indicates that childhood, likewise, is a unique developmental stage of humans. Childhood is the period following weaning, when youngsters still depend on older individuals for feeding and protection (Bogin 1997). Children evidence a relatively larger disproportion between brain size and body/gut size than adults (Bogin 1997). They require a special high-energy diet owing to their rapid brain growth, the continued presence of their deciduous dentition, and their small digestive tracts. The eruption of their first permanent molars and the completion of their brain growth (in weight) mark the transition to the juvenile stage. Juvenile humans have the physical and cognitive abilities needed to acquire much of their own food and to protect themselves from environmental dangers such as predation and disease (Blurton-Jones 1993). Cognitively speaking,

the age of seven in human children equates with the beginning of Piaget's concrete operational stage (Piaget 1983).

Hence, the protracted immaturity period in humans can be explained by the extension of the juvenile and adolescent stages and the addition of the childhood stage. However, the duration of the infancy stage in humans has shrunk compared to that observed in our closest cousin, the chimpanzee. Apes, like, chimpanzees, show a pattern of brain growth that is rapid before birth and relatively slower after birth, whereas humans exhibit rapid brain growth before and after birth (Bogin 1997). Young nonhuman primates' weaning age, in days, is equal to 2.71 times their mother's body weight in grams (Dettwyler 1995). Interpolating from comparisons among nonhuman primates, human should have an average weaning age between 2.8 and 3.7, as opposed to 4.9 years old in chimpanzees. The average age of weaning is 3 years old in non-Western traditional societies, namely small-scale horticultural and hunter-gatherer populations (Johnson 2012). It is important to keep in mind that humans lived in hunter-gatherer societies for over 99% of the evolutionary history of the *Homo* genus (Chapais 2011). Among traditional human subsistence societies, infancy lasts from birth to 30–36 months of age, childhood, from 3 to 7 years old, the juvenile stage, from 7 to 10 for girls and 12 for boys, and adolescence, until 18 for girls and 21 for boys (Bogin 2009). According to UNICEF, half of the world's population continues breastfeeding until at least age two. Contrastingly, fewer than 15% of Americans (and 25% of Canadians) continue nursing their infants after only 6 months of age (Johnson 2012).

The average period between successful births is 5.6 years in wild chimpanzees and 3.6 years in the !Kung, a traditional hunting and gathering society located in southern Africa (Bogin 1990). In theory, humans can have one child per year since breastfeeding is an unreliable ovulation-suppression mechanism in our species. Even if humans mature later than chimpanzees both sexually and socially, their smaller gap between births and longer lifespan give them greater fertility than apes.

Adaptive Value of the Childhood Stage

Three reasons are traditionally cited to explain childhood (Bogin 1997), namely (1) an extended period for brain growth; (2) time to acquire techniques and skills (tool making, food processing, etc.); and (3) time for socialization, play, and the development of complex social roles and cultural behavior. However, as Bogin (1997) notes, these functions could be covered by any of the other stages. Bogin instead posits childhood as an evolutionary strategy to elicit caring from others (juveniles, adolescents, adults, grandmothers, etc.), thus enabling children to develop new skills suited to their environmental conditions while freeing up their mothers for reproduction, hence diminishing the interbirth interval and increasing reproductive fitness. In terms of allometry, as they grow, human children maintain an infantile appearance (large cranium with a small face and body) that prompts nurturing and caregiving behaviors in older individuals (Lorenz 1971). This care for children by other members of the community in hunter-gatherer societies is not observed in other primates (Lancaster and Lancaster 1983).

The hypothesis set forth here is that childhood (3–7 years of age) is the period during which individuals' interaction with peers and education from adults allows them to learn the cultural rules pertaining to, and develop the skills needed for, cooperation. Human beings considerably set themselves apart from other primates by their ability to cooperate with others. This cooperation is central to all human activities, from the division of social roles to searching for food, caring for children (by other members of the community), and even war.

One of the hallmarks of primates is their large brain in relation to their body size. The traditional explanation for this trait is that a larger brain increases cognitive capacity, thus granting the ability to solve the problems encountered in primates' physical environment. A more recent explanation called the "social brain hypothesis" instead suggests that having a larger brain makes it possible to live in larger organized groups. Hence, humans live in more extended groups than do other primates. After all, collective action

is more effective than individual action. One of the main advantages of large groups is the greater protection they provide against predators. Among our ancestors, large groups also enabled the emergence of collective large-game hunting – our ecological niche. However, this coordinated activity raises the problem of how to fairly portion out the meat after the hunt. Indeed, fairness is a prerequisite for continued cooperation. To address this, it became helpful for humans to develop an understanding of the actions, intentions, and beliefs of others of their kind. The ability to step into others' shoes to try to grasp their intentions helps not only detect cheaters, but also mislead and manipulate others while avoiding detection. This manipulation and misleading ability has been referred to by primatologists as Machiavellian intelligence. The ability of social animals, and humans in particular, to catch onto clues enabling them to form a mental picture of what is going on in other people's minds is referred to by psychologists as "theory of mind." The strong correlation observed between neocortical ratio and group size in non-human primates has helped determine, by extrapolation, that humans are capable of memorizing and understanding interrelationships (family ties, alliances, etc.) between 150 individuals (Dunbar 1993). Children's more frequent interactions with other members of the community within a caregiving context offer an ideal setting in which to safely acquire many social skills of all kinds.

Although nonhuman primates are also able to imagine the mental states of their fellow primates, in Tomasello's (2014) view, humans have a more sophisticated theory of mind and can better picture the goals and intentions of other members of their species. According to Tomasello's shared intentionality hypothesis, humans' significant capacity for cooperation relies on the ability to engage in joint attention to achieve joint goals and collective group goals. Chimpanzees have individual intentionality: they are individualistic and competitive, and focus on getting food for themselves rather than engaging in joint attention. Chimpanzees understand that others have goals, and sometimes even help others achieve them, but they do not collaborate with others through a joint goal. Environmental circumstances have forced

humans to become more cooperative and to coordinate to achieve joint goals and collective group goals. Tomasello (2014) refers to joint intentionality when the cooperation is dyadic, and collective intentionality when it involves the cultural group. Collective intentionality likely emerged when human populations began growing and competing with one another. The development of cultural conventions, norms, and institutions would thus have been made possible by language, which enables a higher degree of abstraction.

Still according to Tomasello (2014), in order to solve concrete problems of social coordination, joint intentionality requires the development of specific skills: new forms of cognitive representation (perspectival and symbolic), inference (socially recursive), and self-monitoring (regulating one's actions from the standpoint of a cooperative partner). Chimpanzees make intuitive inferences about their experience (simulating the causes and outcomes of physical and social situations), but not inferences about what others are thinking about their own thinking. The socially recursive inferences begin when humans attempt to coordinate their actions and attention with others in collaborative activities with joint goals and attention.

Linguistic communication in humans paved the way for the development of skills specifically geared toward collective intentionality, i.e., reflective inferences and normative self-monitoring (Tomasello 2014). Reflective inference has to do with the discursive process by which each individual presents, justifies, and argues their ideas or beliefs to others with a view to a common action to be undertaken by the group. This process of cooperative argumentation, of taking into account diverse potential perspectives, leads to a truth considered as an objective part of external reality, in turn justifying the establishment of social norms that will help better regulate decision-making in the future.

Joint attention and cooperative communication are already present during human infancy. As early as 12 months old, human infants are already cooperative and helpful in an array of situations (Tomasello 2009). Before even being able to speak, infants use pointing and pantomiming to direct others' attention perspectively

and/or symbolically toward items relevant to their joint activity, following which the partner makes cooperative inferences about what was intended. Early helping behavior is an expression of natural inclination to sympathize with others in strife, and is mediated by empathetic concern as opposed to resulting from socialization practices. "After their initial period of a kind of indiscriminate altruism mixed with some selfishness about valuable things, young children become more discerning based on various characteristics of potential targets of their altruism. Several recent studies have shown that children begin to make these judgments about others from around 3 years of age. . . . Children of this age more often help those who have been helpful to others" (Tomasello 2009, p. 29). In other words, it is at the age of three – i.e., the beginning of childhood, according to Bogin – that children begin to incorporate cultural norms and values through modeling, communication, and instruction. Genuine social norms based on reciprocity emerge in the late preschool period, as children shed their egocentrism and start to view others and themselves as coequal autonomous agents.

Already during infancy, children have a predisposition for competition (aggression) and a predisposition for helpfulness and cooperation (informing and sharing). Clearly, these tendencies in young children are later shaped by socialization. They learn to be selective about who to help, inform, and share with, and to manage the impression they make on others (their public reputation and self) as a way to influence others' actions toward themselves. Children develop joint intentionality skills during infancy, and then collective intentionality skills during childhood when they first begin to understand social norms and other conventional phenomena as products of a collective agreement of sorts.

With the exception of self-recognition in a mirror, which seems to emerge during infancy (around 18 months of age) and is assumed to be a prerequisite for assigning independent mental states to others, most skills required to understand complex social situations, such as perspective-taking, can be observed starting from 4 years of age in humans, which is earlier than in apes.

Adaptive Value of the Juvenile Stage

We hypothesize that humans' longer juvenile phase can be explained by the need to organize the skills learned during childhood into flexible structures so as to be able to adapt to the many and varied social contexts found in different human cultures.

Experience with multiple playmates in a variety of contexts enables children to develop the behavioral flexibility they need to successfully forge alliances and cooperate in groups. Although social skills appear in most humans at preschool age (3–5 years old), the same cannot be said of social competence. Acquiring social competence requires the individual to combine and regulate skills in order to achieve the flexibility to meet goals across a great number and variety of social contexts. Flexibility, then, appears to be the main advantage of humans' protracted growth. A prolonged period of immaturity would allow humans to acquire skills (4–6 years of age) and especially to organize them into flexible structures (7–12 years of age). Behavioral flexibility is the chief characteristic of social competence; it implies a mastery of basic skills, a strong knowledge of social contexts and, ultimately, self-mastery in the face of the choices to be made. Whereas most specific social skills are believed to be developed during childhood, children only seem to integrate these skills into social competence during the juvenile phase. Social competence is an organizational construct in which specific mental skills are developed and regulated in order to be able to perceive and interpret behavior or mental states of self and others to pursue goals in social contexts. A single skill taken alone – for example memorizing the social status of each member of a group – is a poor indicator of future adaptation. Rather, what enables the individual to meet current and future challenges is proficiency with activating, inhibiting, or coordinating their own skills or those of others depending on social information (Waters and Sroufe 1983).

Friendships are a good way to develop social competence. Children with friends are more socially competent than those without; they tend

to be more sociable, cooperative, altruistic, and self-confident (Hartup and Stevens 1997). Starting from 2 years of age, friendships essentially consist in sharing common activities; it is at preschool age (3–5 years) that friendships support the acquisition of new social skills, particularly in the areas of cooperation and conflict resolution. Beginning at school age, both friendship networks and time spent with friends tend to expand (Hartup and Stevens 1997): friends share interests and exercise self-disclosure. Children 6–12 years old spend more time understanding themselves and others within increasingly complex systems of kinship that lead to more or less stable friendships between peers. Indeed, researchers have noted that more than half of friendships among children 6–7 years old are unstable, and this rate of instability holds steady all the way to adult age (Poulin and Chan 2010). Although the stability and quality of friendships during the juvenile stage are a good predictor of adult social adaptation, researchers point out that this developmental period leading to adolescence affords multiple social experiences in which friendships are forged and maintained in accordance with maturation needs: children first seek out friends with which they can share common activities, before searching for more loyal friends toward adolescence. Given that the instability of friendships increases with group size (70% instability in cliques of 2–9 children) (Chan and Poulin 2007), the challenge of creating the stable ties required for survival and reproduction in adult humans, such as managing alliances in large-group settings or forming lasting couples, increases in complexity as the child grows older. Humans are also believed to require more time to hone their skills and to become socially competent before reproduction age.

Adaptive Value of Adolescence

Finally, we hypothesize that humans' protracted adolescence compared to chimpanzees can be explained by the greater variety and complexity of power relationships and alliances among humans. In most animal species, power

relationships are dyadic (involving only two individuals) and based on coercion (aggression and social dominance). A third party's interference in the power relationships of others (politics) is a relatively rare phenomenon observed only in social species with very highly developed brains such as wolves, lions, and the primates (Chapais 1988). The complexity of strategic alliances among chimpanzees even inspired Frans de Waal to write his famed book *Chimpanzee Politics* (de Waal 1982).

In humans, at adolescence, friendships continue to play a significant role in forging a mutual relationship, with an increase in self-disclosure between friends (Hartup and Stevens 1997). Adolescents compete less with friends than with non-friends, and share more than in the juvenile stage (Hartup and Stevens 1997). We suggest that adolescence is a period for experimenting with and forging power relationships and alliances with peers, before competing with adults. Although rough-and-tumble play does not correlate significantly with aggressive interactions in young chimpanzees and young children, it does in adolescence, for both species (Paquette 1994). This means that adolescents' rough-and-tumble play is a mechanism enabling them to establish dyadic dominance while avoiding harm or the intervention of a third party.

Adolescence is the phase during which intrasexual competition for sexual partners begins. Testosterone is the hormone of both libido and social dominance. The dominance hierarchy is most often shaped by a series of aggressive interactions, but once established, it automatically determines priority of access to resources without requiring further attacks between opponents, as each individual knows their place in the hierarchy. Although testosterone increases in both sexes during adolescence, the spike is greater in boys. Boys' more extensive risk-taking (including aggression) compared to girls can be explained by the mechanism of sexual selection; boys are prepared to take significant risks to achieve a higher social standing that will give them access to a greater number of sexual partners. Women, too, compete among themselves for social standing and sexual partners. Women prefer to mate

with men of high status and good reputation and with men with more resources (Paquette 2015). Based on testosterone and risk-taking curves (Paquette 2015), intrasexual competition is more pronounced during adolescence and early adulthood (until 25 years old) than before or after this period. In addition to dominance, leadership also plays a crucial role in humans. According to a review of the literature by van Vugt (2006), no association can be found between dominance and leadership, as they are different forms of power, the first resulting from coercion and the second from influence. Leadership is a form of cooperation between a group and an individual which gives the group a structured approach to achieving a common goal. Finally, in humans, power is not exercised only through coercion (punishment-based control) but also through differential control of goods and services (power of compensation), information (power of knowledge), and symbolic rewards (normative power) (Chapais 1988). These three last types of power depend on individuals' competence in controlling the resources required by others. The most powerful individuals are those boasting the largest number of people who depend on them to meet their needs.

Sex Differences

From 3 years of age, girls and boys interact with same-sex peers more frequently than with opposite-sex peers (Rose and Rudolph 2006). At this age, boys engage in more rough-and-tumble play and war games than girls. Rough-and-tumble play is the most evolutionary ancient and widespread type of social play found among social mammals (Panksepp 1998). It is a proximal mechanism conducive to developing dyadic fighting skills while avoiding culmination into genuine aggression (Paquette 1994). War games are a specificity of humans, and include both play with guns and "pretend" play or role-playing between warriors or superheroes (Costabile et al. 1992). Whereas rough-and-tumble play first and foremost entails physical contact between two partners without requiring objects, war games are above all symbolic and may or may not involve multiple

partners (solitary or social play), with or without toy weapons. The function of this play is not known, but one possibility is that it allows children to engage in higher-level political or strategic learning that teaches them about intergroup power relationships (us vs. them).

Moreover, also at 3 years of age, boys begin to use more physical aggression than girls, and girls to use more relational aggression and to be more prosocial than boys (Paquette et al. 2013). Relational aggression is a form of aggressive verbal behavior used by children to isolate a peer with the goal of expanding the initiator's own network of influence; this type of aggression peaks at puberty (Vaillancourt 2005). Paquette et al. (2013) have also shown that preschool-aged girls are just as competitive for local resources as boys on two competitive dimensions (other-referenced competition and maintenance of dominance hierarchy), and more competitive than boys on task-oriented competition. Other-referenced competition consists in comparing oneself with the aim of outdoing others and winning, whereas task-oriented competition means striving to surpass oneself in achieving a goal.

By 6 years of age, another sex difference emerges: boys develop the tendency to play in large groups (Rose and Rudolph 2006). Rough-and-tumble play between peers peaks between the ages of 8 and 10 (Pellegrini and Smith 1998).

Intimacy and self-disclosure heighten in both sexes as individuals move toward adolescence (Buhrmester and Prager 1995; McNelles and Connolly 1999). Several studies have shown that adolescent girls report higher levels of intimacy in their friendships than boys at approximately age 12–14 years (Buhrmester 1996; Shulman et al. 1997). Bauminger et al. (2008) emphasize the importance of self-disclosure in establishing and maintaining both intimate friendships and romantic relationships. Some researchers have also demonstrated that shared activities lead to intimacy in adolescent boys (Camarena et al. 1990; McNelles and Connolly 1999). Empathy and intimacy, which are linked to both prosociality and leadership (Bauminger et al. 2008; Garaigordobil 2009; Radmacher and Azmitia 2006), are undoubtedly key to the development of mutual trust and

loyalty, and hence important to reciprocal altruism. The theory of reciprocal altruism (Trivers 1971) puts forward an explanation for cooperation and helping behaviors between nonrelatives of the same species. Such altruism consists in a non-simultaneous exchange of services between two unrelated individuals. It evolves in species capable of individual recognition and remembering past events. This behavior is selected over the course of evolution in cases where both individuals receive more than they contribute, e.g., the cost of supporting an ally against an adversary is low compared to the benefits of holding high dominance status.

Conclusion

To sum up, our comparison of different stages of physical growth in mammals has uncovered a typical human stage that distinguishes our species from the other primates, namely childhood – a period between the infancy stage and juvenile stage, spanning the ages of 3 and 7 years – in today's hunter-gatherer societies. This period may connect with the childhood of our nomadic ancestors who lived as hunter-gatherers for nearly two million years, in contrast with most human societies which became sedentary and agriculturally based only 10,000 years ago – a blip in the evolutionary scale.

Based on the theory of social brain and research showing that humans are highly cooperative compared to the other primates, we have also postulated that the adaptive value of childhood is that it enables young people to develop the basic skills needed for cooperation thanks to interaction with peers, and to learn social rules and moral codes thanks to more frequent contact with the other adults in their community.

Drawing inspiration from psychology research, we have suggested that the adaptive value of the juvenile phase (7–11 years old) lies in the integration of previously acquired social skills into social competence, i.e., flexible structures enabling the individual to adapt to an array of social contexts, especially thanks to friendships, which are relatively unstable throughout

human development. Finally, we concluded that the adaptive value of adolescence resides in experimenting with and forging power relationships and alliances with peers, before competing with adults.

Finally, the sexual differences noted in human development have underscored that power relationships take on different forms depending on the sex. Men more strongly tend to exercise hierarchical power among themselves to acquire prestige and self-esteem, whereas women are gradually primed for more egalitarian relationships focused on cooperation with other women. This cooperation between women may take on various forms such as mutual assistance in searching for food, social support, and, very likely, collective caregiving for the community's youngsters during childhood (3–7 years old) to enable young women to invest in new offspring. Males, too, exhibit various forms of cooperation, such as collective hunting and protecting the community against predators and other groups, but probably above all within alliances during conflicts over social status.

Synonyms

[Estrus](#); [Fertile window](#)

Definition

Ovulation occurs when an egg is released from the ovaries and becomes available for fertilization.

Introduction

Conception is most likely to occur within a window of time ending on the day of ovulation (Wilcox et al. 1995). During this time period, evolutionarily advantageous, or sometimes disadvantageous, circumstances arise – for both the woman ovulating and the individuals interacting with the woman who is ovulating.

During Ovulation

A window of peak fertility is a time when the female member of the species makes significant

changes – explicitly or implicitly – to her behavior to increase her odds of conceiving. For example, Beall and Tracy (2013) found that women who were at high conception risk were three and a half times more likely to wear a red or pink shirt than women who were at low conception risk. Present in nonhuman primates and once present in early humans, ovulation is advertised through various mechanisms of coloration – facial redness and hindquarter redness (Jones et al. 2015). Thousands of years later, red and pink are still associated with sexual arousal and romance. The increased likelihood of wearing red or pink during ovulation, while not an explicit choice, suggest that ovulating females would like potential mates to be aware of their fertility status.

While behavior choices made during ovulation can foster favorable interactions with the opposite-sex, the female body undergoes variations that are seemingly perceptible. In a seminal paper in 2007, Miller et al. (2007) discovered lap dancers earned up to US\$170 more during ovulation than any other menstrual phase. Patrons of the venue seemingly were able to distinguish between ovulating, nonovulating, and contracepting females – visual cues of ovulation can be perceived and acted upon by interested males. Further studies have investigated whether women are perceived differently during ovulation. Cobey et al. (2013) using a within-subjects design discovered that men rated their partner as more attractive when she was fertile, more so than when she was nonfertile or using hormonal contraception. Even further, participating women did not rate themselves significantly different throughout the study – perhaps indicating that their male partner's perception of their attractiveness is not reliant on the woman feeling more attractive herself during ovulation.

If conception risk is high, females can be put on the defensive – they must avoid the consequence of unintended pregnancy via rape or sexual assault. Petralia and Gallup had female participants read a sexual assault scenario and found only the ovulating females exhibited an increase in handgrip strength after reading the passage (Petralia and Gallup 2002). This

rape-avoidance mechanism serves to protect females from conceiving with an undesirable mate.

When women are fertile, their preferences for sexual partners is distinct. For example, women prefer the scent of a man with high testosterone (Thornhill et al. 2013); testosterone is the driving hormone in the masculinization of the face, growth of skeletal muscle, increased intrasexual competition abilities, and overall increased sexual fitness (see Thornhill et al. 2013). Therefore, when women are assessing potential mates during ovulation, they are showing increased preferences for characteristics *directly* affected by an increased level of testosterone. Ovulating women prefer high masculinity in the body, voice, and face (see (Thornhill et al. 2013)). Further, fertile women generally prefer taller men, in addition to preferring men exhibiting social behaviors that lend to the ability to compete with other men – and emerge victorious (see (Thornhill et al. 2013)). This preference is so distinct that these preferences vanish in women who are not ovulating – specifically women who are utilizing hormonal contraceptives (Roberts et al. 2013). Hormonal contraception ceases the normal ovulation cycle to prevent unwanted pregnancy. With that cessation in cycling comes an interruption of the adaptive changes in behavior and preferences. However, the changes can resume once the woman discontinues hormonal contraceptive use.

Women at high conception risk engage in various behaviors that either put them in situations that lend to producing high-quality offspring or avoid situations that would result in low-quality offspring. Antfolk and colleagues found women were most disgusted at the idea of an inbreeding description, specifically for situations when they were described as a *participant* in the activity, when they were most fertile (Antfolk et al. 2014). Ovulating females regulate their behavior accordingly to avoid the genetic, and social, consequences of inbreeding. On the contrary, ovulating women show greater sexual interest and fantasize about extra pair copulation during ovulation, compared to the nonovulation phases (Gangestad et al. 2002). This interest in mates aside from their primary partner hints to the notion that the

ovulating female is more inclined to reap the genetic rewards of mating with a male of increased quality, as described above. Further, the same female participants indicated their partner was more likely to exhibit mate-guarding behaviors when they were ovulating, versus other times in their cycle – the partners of normally cycling women regulate their behavior accordingly to prevent the consequences of extra-pair copulation.

Conclusion

During ovulation, females exhibit a cascade of changes to their behavior, their body, and their preferences to further the likelihood of successful conception. Ovulating women have maintained the ability to leak cues of estrus to interested partners, and thousands of years of successful mating strategies shaped preferences for the most desirable mate at the most imperative time.

such as two romantic partners who form a couple, two friends, teacher-student couples, or two co-workers. Their type of relationship can differ, for example, in the degree of intimacy, time spent with each other, situations in which they meet, or their closeness. Such characteristics might affect relationship-related outcomes such as relationship quality (romantic relationships and friendships) or job satisfaction (e.g., employee-supervisor characteristics). Direct and indirect interactions of behaviors of members of the dyad (e.g., reactions in conflict situations, inclination to spend time with the respective dyad member) and characteristics of each dyad member (e.g., expressions in personality traits) are associated with individual and dyadic outcomes (e.g., attraction or relationship satisfaction). Such *dyadic effects* help to understand the relationship between members of a dyad; for example, how two partners deal with a stressor (e.g., *dyadic coping*) affects external criteria beyond the individual's coping behavior.

This entry gives a short overview of theoretical considerations on why dyadic processes play a role in understanding individuals, methodological challenges in the study of dyadic data, and statistical approaches to study dyadic processes. Finally, we will present key findings on three main topics from the field of dyadic research.

Dyadic Processes

Definition and Introduction

A dyad is composed of two people who are interdependently connected by a relationship

Why Studying Dyadic Processes Matters

While psychology aims at describing, explaining, and predicting behavioral, cognitive, and emotional aspects of individuals, humans coexist and interact with others throughout the life span. The social environment contributes to shaping stable dispositions of thoughts, feelings, and behaviors (approximated as personality traits) in private and professional contexts over time – from birth (e.g., interactions with caretakers, siblings) throughout life when dealing with peers, romantic partners, teachers, or colleagues across all domains of life. As people do not exist independently from each other, relationships and dyad members' interdependence have consequences; for example, a robust finding in romantic life is that romantic partners have assortative mating preferences

(i.e., above chance similarity in partners' phenotypes) and show similarity in numerous physical and psychological variables (e.g., Conroy-Beam et al. 2019; Luo 2017). Also, there is strong evidence that one's own but also the partner's personality have an impact on romantic life (e.g., relationship quality) and that joint characteristics of the dyads also play a role. For example, partner similarity contributes positively to relationship satisfaction (i.e., similar couples are happier than dissimilar couples, although usually with small effect sizes; Luo 2017; Weidmann et al. 2016). Overall, social interactions play a role across all life domains (e.g., at work, in the classroom) and for any type of relationship that people form and maintain in those domains (e.g., Chow et al. 2013; Ireland et al. 2010; Liden et al. 2016).

Dyadic interactions have been studied on different levels using various data sources. Studies have examined associations of verbal and nonverbal dyadic behaviors such as the similarity in partners' language use and their inclination to romantic interest (Ireland et al. 2010), the occurrence of couples' joint laughter, and relationship satisfaction (Kurtz and Algoe 2015) or whether mimicking a partner's nonverbal behaviors (e.g., smiling, crossing arms, or hand movements) is associated with liking one's respective partner (Kurzius and Borkenau 2015). Other studies have examined the influence of relatively stable dispositions in dyadic systems such as romantic couples when studying the associations between broad and narrow personality traits, dyadic effects (e.g., partner similarity), and romantic outcomes (e.g., relationship satisfaction; e.g., Brauer and Proyer 2018; Weidmann et al. 2016).

Theoretical considerations on why and how dyadic interactions affect individuals and their relationships have been proposed. For example, in the line of research on adult playfulness, Chick (2001) suggested in his *signal theory of play* that being high in playfulness communicates underlying characteristics such as low aggressiveness in men and high fecundity in women to their potential long-term partners. Therefore, playfulness could be one characteristic that impacts sexual selection. Moreover, potential partners need to accurately perceive and interpret traits in others,

which is also subject to dyadic research, as it seeks antecedents and consequences of interpersonal perception (Connelly and Ones 2010). Indeed, empirical evidence supports Chick's suggestions, as there is evidence that (a) playfulness can be accurately perceived by others, even upon minimal information (i.e., short textual self-descriptions, Proyer and Brauer 2018), (b) romantic partners demonstrate similarity in their playfulness, and (c) individual and dyadic levels of playfulness are related to partners relationship satisfaction (Proyer et al. 2019). This example shows that theories on dyadic processes and their empirical examination are complex and demand multimethodological approaches.

Dyadic interactions can also have negative consequences; for example, peer aggressiveness (*bullying*) is a dyadic phenomenon between the aggressor (bully) and the victim. To understand the conditions under which bullying and victimization occur, it is important to study the individuals involved and their dyadic interactions (see Salmivalli 2010). Consequently, one might argue that interventions should be more effective if they target not only an individual but the dyad (or larger systems; e.g., classrooms, families, work teams).

There are theoretical accounts of how and why social interactions affect both the individuals in the social situation and their relationship reciprocally. For example, the *dynamic interactional paradigm* describes the co-development between individuals' personality and their relationships over time and assumes that people create and maintain their relationships in a way that suits their personality (e.g., Neyer and Asendorpf 2001; Neyer et al. 2015; also see Deventer et al. 2019). However, the social environment might also affect the individuals' personality involved in the relationship over time. Thus, a dynamic process between the individual and its social environment exists that indicates bi-directional effects in the way that the person affects his social environment and how he/she is affected by his/her social environment (so-called *personality-relationship transactions*; Neyer and Asendorpf 2001). There are differential relationships between traits of the individuals, dyadic

interactions, relationship types (e.g., friendship vs. work), and outcomes.

The study of dyadic processes needs specific methodological approaches that account for the interdependent structure of dyadic data. In the following section, we will give a short overview of four statistical approaches to analyze dyadic data, namely, the *Actor-Partner Interdependence Model* (APIM; Cook and Kenny 2005), the *Common Fate Model* (CFM; Ledermann and Kenny 2011), the *Social Relations Model* (SRM; Kenny 1994), and *Response Surface Analysis* (RSA; Edwards 2002).

Statistical Approaches for the Analysis of Dyadic Processes

Unit of analysis. Research on dyadic processes considers data of both dyad members; thus, the unit of analysis is the dyad instead of the number of individuals. The latter are nested into dyads (e.g., two romantic partners form a couple). Therefore, the sample size is defined as $k = N/2$. For example, when collecting data from 400 supervisor-employee dyads, the sample size for the study of the dyadic data is defined as $400/2 = 200$ dyads (see also Kenny et al. 2006). It must be noted that the nested nature of the data affects the statistical power and the degrees of freedom when testing the statistical significance of effect estimates (for an overview on statistical and methodological consequences, see Kenny et al. 2006).

Actor-Partner Interdependence Model. The APIM considers a predictor (e.g., extraversion) and an outcome variable (e.g., satisfaction) for each dyad member. Further, the interdependence of the dyad members' predictor and outcome variables and their error terms is considered. The APIM allows for estimating the association between predictor and outcome variables by two effects: the *actor effect* (i.e., association between partner A's trait expression and partner A's satisfaction; same for partner B) and the *partner effect*, which describes the association of the predictor variable of partner A with partner B's outcome. For illustration, one might think of studying the relation between extraversion (predictor) and

relationship satisfaction (outcome); the actor effects describe the association between partner A's extraversion and his/her own satisfaction as well as the relation between partner B's extraversion and his/her own satisfaction. More interestingly, the partner effects describe how partner A's extraversion is related to partner B's satisfaction as well as the association between partner B's extraversion and A's satisfaction, which allows for examining how each dyad member contributes to their own satisfaction while also considering the partner's contribution under control of their interdependence (e.g., similarity in predictors and outcomes). Overall, the literature has shown that partner effects are typically numerically smaller than actor effects but show incremental value (Weidmann et al. 2016).

Further, researchers might be interested in how partners affect each other. Kenny and Ledermann (2009) proposed a method to examine the existence of particular *dyadic patterns*: the *actor-only* pattern (i.e., only actor effects but no partner effects exist within the dyad), the *partner-only* pattern (i.e., only partner effects but no actor effects exist within the dyad), the *couple* pattern (i.e., actor and partner effects exist), and the *contrast* pattern (i.e., actor and partner effects exist but are in the opposite direction; e.g., positive actor but negative partner effects).

The APIM also allows for adding dyad-level variables such as an interaction term (e.g., interaction of partner A's and partner B's extraversion) or an index of similarity (e.g., absolute differences between partners' extraversion or profile similarity across a number of traits) to estimate the magnitude of dyadic effects over and above each member's contribution to their respective outcomes. This overcomes methodological fallacies that might bias the findings, as ignoring the main effects of actors' and partners' predictors leads to overestimation of dyadic effects. For example, previous literature on the role of dyadic similarity (e.g., in personality, attitudes, and values) overestimated the role of similarity for relationship satisfaction (see Luo 2017; Weidmann et al. 2016). Thus, dyadic research should utilize methods that partition variance into effects of actors, partners, and their relationship.

Finally, the APIM can be extended to implement mediator variables (*Actor-Partner Interdependence Mediation Model*, APIMeM; Ledermann et al. 2011). The APIMeM allows for examining the effects of both partners' mediator variables and estimates how they affect partner A's and partner B's actor and partner effects. The APIMeM has helped to extend knowledge on which mechanisms and processes underlie dyadic interactions and their associations with external outcomes (e.g., the mediating role of interpersonal competence for the association between empathy and relationship quality in friendships; Chow et al. 2013).

Overall, the APIM is a popular and useful approach to study dyadic relationships, and its extensions allow for modeling the complexity of a variety of research questions when investigating dyadic processes. Researchers can choose whether the APIM is estimated by means of structural equation modeling or multi-level modeling (Kenny et al. 2006).

Common Fate Model. In comparison with the APIM, which examines the dyad in terms of each member's predictors and outcomes separately, the CFM allows for analyzing variables that are composed of both members' views (Kenny and Ledermann 2012). For illustration, one might think of the construct of *dyadic coping*, which describes how romantic partners deal with stressors in their relationship. Since both members contribute to how they jointly cope with stress, the construct should cover the views of both partners, and thus ratings of each partner are needed. The CFM treats a dyad-level construct as a latent variable, which is estimated using both members' responses as manifest indicators (Kenny and Ledermann 2012).

Further, the CFM can be utilized to describe dyadic processes over time (e.g., estimating change in dyadic coping between two time points) as well as effects of a dyadic predictor on a dyadic outcome (e.g., how does understanding each other affects relationship harmony; see Kenny and Ledermann 2012). Further, researchers might be interested in examining relationships between individual- and dyad-level variables, for example, when testing how each dyad member is affected

by a jointly experienced life event (e.g., child loss). In this case, hybrid models combining the APIM and CFM are available. Interested readers are referred to Kenny and Ledermann 2012), who discuss applications and examples for the usage of the CFM and its distinctions from the APIM. The CFM is computed by using structural equation modeling.

Social Relations Model. The SRM allows for analyzing three components of interest in dyadic research questions (As a technical note, it must be mentioned that an error term is computed as a fourth effect in the SRM, but this is not considered in further detail here. See Back and Kenny (2010) and Kenny (1994) for more information.), namely, the actor and partner effects and a relationship effect, which characterizes the unique interaction between an actor and his/her partner. In contrast to the previously described approaches, the SRM is based on more than one interaction of participants. Hence, each participant rates k partners and receives a reciprocal rating by each partner.

While the SRM allows for studying numerous variables (e.g., ratings of personality or behavioral acts), we will illustrate its effects with a study on interpersonal liking. Consider a group of four participants who meet for the first time and interact with each other for 5 min. Afterward, each of the four participants (Denis, Franz, Kira, and Maria) give ratings on how well they like their respective group members (A research design in which all participants provide and receive reciprocal ratings is called *round-robin design*. An alternative design is the *block design* that considers asymmetric combinations of participants (e.g., only reciprocal ratings between males and females).). Thus, there is data on how every participant is liked by their group members as well as how every member likes his/her respective group members. The SRM estimates three effects for each actor, each partner, and each interaction between two members. For example, the actor effect of Kira describes her general tendency to like others, whereas her partner effect describes how she is liked on average by the other three members. Similarly, actor and partner effects can be computed for Denis, Franz, and Maria. To capture the dyadic component of each interaction

between the four participants, a *relationship effect* is computed. This dyadic effect indicates how much variance is explained by the unique dyadic process between two persons while general tendencies of viewing others (actor effect) and being viewed by others (partner effect) are controlled. Thus, the three variance components give a first impression of the explanatory value of actors, partners, and their unique dyadic relationship.

The SRM allows for extending analyses toward the dyadic process of *reciprocity*. Firstly, the *generalized reciprocity* is computed as the correlation between actor and partner effects. Considering our example of liking, the generalized reciprocity informs how well liking others (actor effect) converges with being liked by others (partner effect) across the sample. A positive correlation would indicate that, on average, people who like others are also liked by others while participants who dislike others are also disliked by others. Hence, this describes trends across all studied dyads. Secondly, *dyadic reciprocity* is the correlation between dyad members' relationship effects. This allows for estimating the convergence of the unique liking between two members. While the description and example illustrated the SRM when studying a single variable (liking), the model can be extended to bivariate analyses. For example, one might be interested in how liking is related with the willingness to enter a romantic relationship with an interaction partner (see Back and Kenny 2010; Kenny 1994). Overall, the SRM estimates dyadic processes in complex ways and helps to understand the role of individuals and their relationship characteristics.

Response Surface Analysis. Finally, researchers might be interested in the *interplay* of two dyad members' attributes (e.g., expressions in personality traits, attitudes, values, etc.) to predict an outcome of one dyad member (e.g., one partner's satisfaction) or the dyad (e.g., dyadic coping). RSA allows for a fine-grained analysis of such effects on a third variable by using *both* dyad members' data in a polynomial regression model that describes a three-dimensional space (i.e., X/Y-axis = scores of partner A/B and Z-axis = outcome variable). RSA is often utilized to examine the convergence between members'

scores (e.g., similarity or agreement) and its effects on outcomes. A merit of RSA is the usage of the full information of both members' instead of transforming them into a dyadic index by means of an algebraic, absolute, or squared difference (Edwards 2002). This approach overcomes psychometric disadvantages of difference scores (e.g., loss of reliability, untested constraints, confounded main effects; see Edwards 2002) and describes the complexity of dyadic congruence and incongruence and its effects on criterion variables. While the standard RSA considers both dyad members' predictor scores, only one outcome can be predicted. Since researchers are often interested in how dyadic convergence affects both members' outcomes, the *dyadic response surface model* (DRSA; Schönbrodt et al. 2018) has been introduced to allow for the full dyadic analysis of predictors and outcomes by combining RSA with the APIM. Examples and computation guidelines can be found in Barranti et al. (2017) and Humberg et al. (2019).

Key Findings of Dyadic Processes

The methods described above have been utilized for a broad range of studies on dyadic processes using numerous methods and designs (e.g., behavioral measures, self-, peer, or partner reports). We will give a short overview of key findings from three major lines of research in dyadic research: the study of dyadic similarity (i.e., how dyad members resemble each other), interpersonal perception (i.e., how accurately dyad members perceive others' traits), and co-development (i.e., does the individual affect its social network and/or does the social network affect the individual that is embedded in its social network).

Similarity. As mentioned previously, the role of similarity has been studied in dyadic research across types of relationships with respect to two key issues: (1) describing the similarity between two people and (2) testing whether similarity affects outcomes (e.g., are similar couples happier than dissimilar couples?). In sum, the literature supports the notion that relationships are

characterized by partner similarity instead of complementarity across a wide range of variables such as age, intelligence, attitudes, personality traits, and habitual behaviors (e.g., hobbies; for an overview see Luo 2017). Recently, this robust finding has been replicated across 45 countries (Conroy-Beam et al. 2019). It has been suggested that similarity contributes to low disagreement in couples, as they share similar views and behave accordingly, which reduces the potential for disagreement, facilitates satisfaction, and thereby contributes to healthy and positive relationships. However, the literature shows that similarity has only small effects on outcomes beyond the contribution of actor and partner effects (Luo 2017; e.g., Brauer and Proyer 2018; Proyer et al. 2019; Weidmann et al. 2016).

Interpersonal Perception. When people interact, they form impressions about others (e.g., their personality traits or intelligence) in order to predict and estimate their future behaviors. Such judgments occur across life domains and types of acquaintanceship – for example, when teachers form impressions about students, supervisors about their employees’ performance, or when making judgments about potential partners. Thus, perceptions of others concern a typical dyadic research question. In this line of research, the dyad is composed of a *target* person who is judged by an *observer* (also called *perceiver* or *judge*). Overall, the literature has shown that people can infer others’ traits accurately and above chance, even when making inferences about strangers at zero acquaintance (e.g., Proyer and Brauer 2018; for an overview see Connelly and Ones 2010). While most interpersonal perception studies analyze the overlap between targets’ self-ratings and observer ratings (*self-other agreement*), there is robust evidence that judgments possess predictive validity for naturalistic outcomes such as academic achievements or job performance (Connelly and Ones 2010; also see Ambady and Rosenthal 1992).

Overall, it is suggested that accurate judgments about others facilitate everyday decision-making across all domains of life and have consequences for both the judge and the judged person as mate choices, hiring decisions, or student evaluations

are based on interpersonal perceptions. Finally, the field has provided evidence that moderating variables such as the length of the acquaintanceship, the evaluativeness and observability of traits, as well as characteristics of targets and judges affect the goodness of perceptions (Connelly and Ones 2010). Taking previously mentioned findings into account, accurate perceptions of others are the prerequisite to finding partners who show desired characteristics and/or are similar to oneself.

Co-development. Since people are embedded in social systems in private and work life, it has been argued that dynamic transactions between the social environment (e.g., peers, teachers, or romantic partners) and the individual exist (cf. “Why Studying Dyadic Processes Matters”). There is robust evidence for this assumption, as longitudinal studies examining the dynamic relationships between the individual and its social network support the notion that people choose and maintain relationships that suit their personality (i.e., selection effects) and that the social environment affects the individuals over time (i.e., socialization effects; Neyer et al. 2015 and Wrzus and Neyer 2016). The findings indicate that changes in personality traits predict changes in social network characteristics and vice versa. Thus, social interaction and its underlying dyadic processes affect how personality is shaped, while the personality of those within the social network contributes to shaping and maintaining the social relationships.

Conclusion

The description and study of dyadic processes is a complex topic because researchers are faced with additional methodological challenges to account for the interdependent nature of dyad members’ predictor and outcome variables while accounting for their unique dyadic relationships. Within the realm of available methods, researchers must choose the appropriate analysis procedure depending on their research question and design.

However, the presented findings underscore that people exist and develop within social

networks across all areas of life. There is broad evidence that actors' outcomes, such as happiness and satisfaction, are also uniquely affected by their partners (e.g., peers, romantic partners, family members) or characteristics of the relationships (e.g., similarity, length of acquaintance). Thus, to truly meet psychology's core aims of describing, understanding, explaining, and predicting humans' patterns of behaving, thinking, and feeling, it is advisable to extend studies toward people's interpersonal relationships and examine their role for the individual.

Dyadic Relationships Versus Group Processes

Julie Fitness and Trevor I. Case
Macquarie University, Sydney, NSW, Australia

Synonyms

Group living; Marriage; Pair bonds

Definition

A dyadic relationship comprises two individuals who are more or less interdependent and who need one another to facilitate their survival and reproductive goals. Groups comprise three or more similarly interdependent individuals who may or may not be related, and who cooperate with one another to achieve common goals. Both dyads and groups may experience conflict when self-interest trumps mutual benefit. Groups also compete with each other for control of resources.

Introduction

From the moment of birth, humans have been crafted by evolution to desire relationships with those who are best placed to meet their needs, and to find happiness and security in the company of those who value and care about them. Further, and in the interests of successful reproduction, humans possess powerful motivations to establish committed pair-bond relationships that facilitate the survival of offspring. From an evolutionary perspective, then, humans are equipped with the psychological mechanisms required to successfully engage with their social world and to meet its challenges and opportunities.

To what extent might these mechanisms be specific to particular kinds of relationship and group contexts? Unlike social groups, for example, pair-bond relationships are characterized by proximal, mating-relevant interests and goals, such as the need to secure partner commitment, negotiate relationship threats such as the availability of attractive alternatives, and successfully manage the exigencies of raising offspring. On the other hand, a variety of processes occur within and between social groups such as stigmatization, social exclusion, prejudice, and warfare that would seem to have little relevance to either pair bonds or other types of dyadic relationships, such as friendships. However, there are aspects of both dyadic and group relationships that present the same, basic challenges to their successful functioning, such as competition for resources, the need for cooperation, and the costs of betrayal. It

seems likely that some of the adaptive psychological mechanisms that have helped humans meet these and other social challenges over the course of their evolutionary history operate in both dyadic and larger group contexts. Our aim in this chapter is to briefly discuss some of the unique and shared aspects of dyadic relationships and group processes, and to examine the critical role of emotions as evolved psychological mechanisms that facilitate both dyadic and group functioning.

Dyadic Relationships: The Formation and Maintenance of the Pair Bond

Social psychologists have long been interested in the phenomenon of interpersonal attraction, and what draws people to one another (Berscheid and Reis 1998). There is now a large body of research demonstrating the fundamental features of social selection amongst humans, each of which is potentially adaptive for their welfare and survival (Barclay 2016). One important feature is familiarity, signaling safety and predictability, while another is perceived similarity, signaling rewards such as reciprocity of attraction and, potentially, genetic relatedness (see Kurland and Gaulin 2005). A third feature is physical attractiveness, including facial symmetry and signs of good health (and potentially, fertility). This latter feature is particularly relevant in the context of sexual selection, but also plays a more general role in social selection, with cross-cultural research demonstrating that physically attractive individuals (including children) tend to enjoy higher status and attract preferential treatment from others (Langlois et al. 2000). One explanation for this evolved preference is that people implicitly associate physical attractiveness with other positive qualities such as intelligence, kindness, and success in life. At a proximal level, these qualities enhance the desirability of attractive individuals both as friends and mating partners. At a more fundamental level, it appears that humans possess an evolved psychological mechanism that drives both affiliative and mating preferences towards others who, on the basis of their physical

attractiveness, are relatively “good bets” with respect to also possessing superior health and resources (Fitness et al. 2003).

There are, however, aspects of mate selection that distinguish it from other kinds of social selection. Specifically, and as Buss (1989) demonstrated in his cross-cultural research, both men and women place primary importance on emotional stability and kindness in a potential mating partner. These are important safety signals given the risks of exploitation and betrayal in a sexually intimate relationship. However, men and women differ with respect to the importance they place on the desirability of physical attractiveness and the possession of resources, including status. Specifically, and in line with their reproductive interests, men’s mating preferences tend toward relatively young, physically attractive (and likely fertile) women, while women’s mating preferences tend toward older men with the resources to support their offspring. Even so, there are important caveats to these general preferences, depending on context. For example, women who are seeking short-term rather than long-term mating opportunities, may, like men, place relatively more importance on “good genes,” signaled via physical attractiveness, than on resources (Buss and Schmitt 1993).

Another mating-specific psychological mechanism that effectively switches off mate-seeking motivations and switches on commitment to the current mate is the intense and sometimes overwhelming experience of romantic love (see Fletcher et al. 2015). Romantic love is theorized to comprise two evolved systems with discrete functions. The first system, passionate love, integrates sexual desire with deep longing for, and obsession with, a mating partner. The evolved function of passionate love is to motivate mating, the ultimate outcome being the successful transmission of an individual’s genes to the next generation. The second evolved system, attachment love, may be further divided into two subsystems. The first is nurturing, or care-giving love, the primary function of which is to provide offspring with the unconditional commitment they require to survive and thrive. However, romantic lovers also nurture and care for one

another when necessary, and powerful feelings of tenderness may be aroused by a partner's perceived vulnerability (Fitness 2015). The second subsystem of attachment-love is intimate, or "companionate," love characterized by strong emotional bonds and commitment, the function of which is to facilitate the maintenance of the pair bond over time and provide an environment conducive for successful reproduction and child-rearing (Berscheid 2010).

It has been proposed that the human attachment system is the "*sine qua non*" of both parent-child relationships and adult pair bonds (see Gillath et al. 2016, for a review of the voluminous literature on this topic). Further, attachment processes are also active within close, platonic friendships, particularly during adolescence, when young adults may shift some attachment functions from their parents to one or more close friends (Gillath et al. 2016). This may be especially true for young women, whose same-sex attachment bonds are frequently emotionally intense, intimate, and long-lasting. It has been proposed that these intimate bonds between women are adaptive psychological mechanisms derived from an evolved history of exogenous mating; i.e., women have frequently had to leave their own kinship groups and join their mates' groups (Vigil 2007). Under these circumstances, and in the potential absence of adequate partner support, women needed (and arguably still need) the care and support of one another for successful child-rearing (Sear 2016). Support for this hypothesis is strengthened by the observation that in general, men's friendships with one another tend not to involve the same kinds of emotional intimacy and companionate love as women's closest friendships (Fehr 1996). As will be discussed later in this chapter, men tend to have different requirements for friendships that involve the coordination of shared goals and activities (see also Kurzban and Neuberg 2005). At any stage of life, however, both men and women may develop close, same-sex friendships characterized by nurturance, intimacy, and trust, with the warmth and love associated with these relationships providing a significant source of ongoing, mutual support.

Conflict in Dyadic Relationships

As discussed above, close relationships such as the pair-bond, close friend, and parent-child relationships are the source of some of our most powerful and positive emotional experiences. However, as noted by Shakespeare, "the course of true love never did run smooth," and these close relationships also provide the context for some of the most painful emotions that humans can experience (see Fitness 2015). Romantic jealousy, for example, is a powerful emotion experienced by individuals in every culture in response to the perceived diversion of resources (including sex and love) to a rival. Further, and in line with their reproductive interests, there are reliable sex differences with respect to the events that trigger the most intense jealousy. Specifically, and in line with the threat of paternity uncertainty, men are most incensed by a partner's sexual infidelity, whereas women are most threatened by a partner's deep emotional attachment to a rival that might, in turn, lead to the loss of commitment and resources (Buss 2018). Similarly, sex differences have been found with respect to the types of deception that men and women find most upsetting. For example, women are more upset and angry than men by their partner's concealment of an emotional bond with other women, while men are more upset and angry than women when their partner is sexually unfaithful in the context of a long-term relationship (Haselton et al. 2005).

Clearly, romantic love and romantic jealousy are potentially adaptive psychological mechanisms, shaped by natural selection to facilitate mating and mate-guarding. However, humans possess a range of other discrete emotion systems that motivate potentially adaptive behaviors in the close relationship context. Ellis and Malamuth (2000), for example, demonstrated that feelings of love and anger in married couples operate independently of one another, with love tracking strategic facilitation (how well is my partner meeting my needs?) and motivating continued commitment, and anger tracking strategic interference (my partner is blocking my desires and goals) and motivating behaviors to remove the blockage,

some of which may involve aggression and violence.

Perhaps the most potent sources of anger in dyadic relationships derive from perceived exploitation and acts of betrayal. Close relationships are characterized by both partner interdependence and communal norms and values, such as mutual responsiveness to each other's needs. In communal relationship, partners do not keep close track of costs and benefits as they would in an exchange or quid pro quo relationship (such as with the plumber in an employment relationship). Rather, they trust that their partners are committed to their welfare and will act in their best interests (Clark et al. 2001). However, high trust also means high risk, and vulnerability to the possibility that one's partner may cheat (e.g., by taking more resources than they invest; see Shackelford and Buss 1996). Such perceived inequities are a major cause of anger and marital dissatisfaction (Sprecher 2018).

Acts of betrayal, too, may range from the relatively minor, such as ignoring a partner's wishes or failing to consult about what should be a joint decision, to physical and/or sexual abuse, infidelity, deception, and desertion (Fitness 2001). Such violations of relational "rules" and expectations may generate not just anger but a range of other powerful emotions such as fear, grief, or even hatred, depending on how the injured partner appraises the threat to their welfare. Hurt, for example, tracks partners' perceived investment in the relationship and is elicited in response to behaviors signaling that one's partner does not value the relationship as much as had been assumed (Fitness 2015). The pain of relational hurt may be experienced as traumatic, with the devalued partner experiencing the shame and fear of being found unlovable and unworthy in what was meant to be a secure, safe haven.

Once a relational rule has been violated, an injured partner can choose either to maintain the relationship or terminate it, and this decision depends on a number of factors. For example, if the violation has been appraised as relatively severe and/or re-occurring, then termination may be seen as the most adaptive option (particularly if there are attractive alternatives available). From

an evolutionary perspective, however, it may also make sense to "kiss and make up" if partners are heavily invested in the relationship and there are still tangible benefits, such as security or shared child-rearing responsibilities, that outweigh the costs, such as emotional pain. An evolved propensity to forgive and reconcile with close others clearly has adaptive value and plays an essential role in the maintenance of important relationships, especially among kin and between pair bonds. However, forgiving also involves the risk of further offending and exploitation of the forgiver; hence, the process of forgiveness does not imply that there are no costs imposed on the offending partner (see Fitness and Peterson 2008). Indeed, one of the defining features of anger is the motivation, not just to remove an obstruction to one's goals but also to punish the perceived cause of the obstruction.

From an evolutionary perspective, punishment serves a behavioral deterrence function, signaling aversive outcomes of repeat offences. In the proximal context, punishment restores some power to the punisher and importantly, may feel good, even when personally costly (e.g., cutting off one's nose to spite one's face). In a study of marital betrayal and forgiveness, Fitness (2001) found that a range of punishments had been imposed on offending partners, from the relatively mild (e.g., regular reminders of the offence, publically telling family and friends about it) to the more serious (e.g., exclusion and "the silent treatment," verbal and physical abuse). Some of the latter punishments became hurtful relational transgressions in their own right foreclosing possibilities of reconciliation as partners become trapped in escalating cycles of conflict (see also Gottman and Driver 2005).

In summary, couples in close relationships are challenged by the need to deter exploitation and future harm via punishment, with restoring relationship benefits via forgiveness. Different emotion systems can help them to do that. Being in love, for example, helps partners to put a "positive spin" on each other's shortcomings and facilitates charitable explanations for partner offences (Fitness et al. 2003). Similarly, genuine displays of an offending partner's guilt and remorse may

motivate empathy and compassion and facilitate forgiveness (Fitness 2001). However, there is still much to be learned about the ways in which dyadic partners manage these delicate negotiations in the interests of recalibrating their relationships, and the potential role of powerful avoidance emotions like hatred, contempt, disgust, and shame, in shutting down such negotiations entirely.

Group Processes and Intergroup Conflict

Just as no individual or dyad can survive alone, so too do humans need the support of groups within which they can share resources for their mutual benefit and protection (Van Vugt and Schaller 2008). It has been proposed that, just as humans have evolved psychological mechanisms to facilitate pair bonding and parental care, so too have they evolved psychological mechanisms that facilitate their capacity for living in groups (Kurzban and Neuberg 2005). For example, one of the most important aspects of group living involves the willingness of group members to cooperate with one another and to reciprocate valued resources. Given that the willingness to co-operate necessarily entails some self-sacrifice, it is important when advertising oneself as a potentially desirable group member to demonstrate qualities of unselfishness, trustworthiness, and commitment to the group. As noted previously, these qualities are also highly attractive in the dyadic context, whether one is “in the market” for a mating partner or a close friend (Barclay 2016). Similarly, in both social contexts there is the risk of false advertising, and in both contexts humans are finely attuned to the identification and punishment of cheats who threaten the welfare of the dyad or the group (Shackelford and Buss 1996; Van Vugt and Schaller 2008).

Further, in the course of group formation and maintenance, group members become increasingly interdependent with the associated benefits and costs that such interdependence entails. For example, being accepted into valued groups is rewarding, and collaborative group interactions have the potential to generate happiness and joy,

emotions that build and strengthen friendships and attachment relationships (Fitness 2015). However, and as noted above, to the extent that group members develop broad and deep interdependencies, so too do they become vulnerable, just as dyadic partners do, to the risks of betrayal. Further, just as such violations of relationship “rules” generate powerful emotional responses in dyadic relationships, so too within groups do such threats activate emotional responses such as anger, with its corresponding motivations and behaviors, including punishment of offending group members. Indeed, the motivation to punish traitors who are perceived to have acted against the interests of the group (and potentially delivered them to a hostile outgroup) is especially powerful (Kurzban and Neuberg 2005). The Italian poet Dante, for example, assigned traitors to the lowest and coldest regions of Hell, to be forever frozen up to their necks in a lake of ice as punishment for having behaved so heinously. In line with the theme of “freezing out,” one of the most frequent punishments for perceived offences by an in-group member is social exclusion and ostracism. These are particularly severe penalties given the fundamental human needs for belonging and protection. As noted previously, close relationship partners may also use this form of punishment, with “the silent treatment” having been described by some relationship partners as worse than abuse (which at least reminds them that they exist; see Williams et al. 2005).

Perhaps one of the most powerful group contexts that exemplifies the rewards and costs of group living is the family. Families are prototypically communal contexts, characterized by complex interdependencies and shared responsibilities for each other’s welfare. Further, the benefits and costs of family life are particularly potent because family members typically are genetically related to one another by varying degrees and so must frequently negotiate conflicts between the competing demands of self-interest (e.g., when a child would prefer to monopolize parental resources) and self-sacrifice (e.g., when the same child is required to share resources to facilitate the survival of a brother or sister (see Kurland and Gaulin 2005)). One important implication of this conflict

is that for self-sacrifice to be worthwhile, family members must be sure that they are, in fact, genetically related to one another. In one investigation of favored and disfavored family members (Fitness 2005), respondents reported that the primary reason for their “black sheep” status was either explicit genetic unrelatedness (i.e., they were adopted) or that they were perceived by other family members to be “different” and to not “fit in.” This was in contrast to favored family members, who were more likely to report talent, “goodness,” likability, and similarity to the parent as reasons for their favored status. As noted in the discussion of interpersonal attraction, similarity is a fundamental feature of acceptability to others, signaling mutual rewards and in the context of kin selection, likely genetic relatedness. Further, just as social exclusion is a prominent feature of dyadic and within-group punishment, so too the consequences for familial black sheep were frequently severe, ranging from total exclusion to “chilly” politeness, reminding them of their “outsider” status. Clearly and despite the mythology of the family as a “safe haven” characterized by unconditional love and forgiveness, like every other group, families have rules, boundaries, and punishments. The costs of exclusion are decidedly higher, however, than expulsion from one’s book club and may contribute to lifelong feelings of shame, anger, and depression (Fitness 2005).

Just as competition for scarce resources can generate within-group tension and conflict, so too can competition *between* groups generate intense rage, hatred, and contempt, unmitigated by any history of cooperation or shared fate. Based in part on the strength of these emotional responses, Kurzban and Neuberg (2005) suggested that there may be specific adaptations serving group-based competition functions, such as enhanced within-group cooperation when under threat from an outgroup, and the formation of strong coalitional bonds amongst men, motivating aggression and warfare. Importantly, they also noted that the most severe forms of antisocial behavior tend to be targeted toward groups that are perceived to be internally coordinated and cooperative, implying that tightly-knit kinship groups may be perceived by other kinship groups,

or tribes, to represent the most threatening categories of “outsiders.” Cottrell and Neuberg (2005) further argued that a threat-based framework is useful for predicting the emotional responses of in-group members, such as fear or outrage, to particular outgroups, with specific emotions activated in response to specific kinds of perceived threats. Outgroups that are perceived as threats to physical safety, for example, will elicit fear within the in-group; those that threaten in-group resources will elicit anger; and those that appear to threaten health or in-group morals will generate disgust. In this way, the same fundamental emotion systems that operate within dyadic and in-group contexts may be co-opted for service in the context of out-group hostility, derogation, and even genocide.

Conclusion

As noted throughout this chapter, the emotional responses of humans in any kind of social relationship provide a rich source of information about their perceptions, interests, and goals. It should be noted, however, that the emphasis in much of the work on within-group and intergroup processes has focused on threats and challenges, leaving gaps in our understanding of the potential roles other emotions may play in both enriching within-group relationships and encouraging more conciliatory relationships with outgroups. For example, and as discussed previously, emotions such as liking, love, and joy feature prominently within dyads and groups, signaling that needs and goals are being facilitated, and strengthening bonds. Further, couples, family members, and close friends may frequently experience the relationship-enhancing emotions of pride, admiration, and gratitude in relation to one another (Fitness 2015). Unfortunately, the corollary to these warm, within-group feelings may be cold, hostile feelings toward outgroups. Researchers are speculating on the potential roles of compassion, guilt, and empathy as ways of breaking down perceptions of “other-ness” and acknowledging out-group members’ common needs and interests (e.g., see Goetz et al. 2010; Karaçanta

and Fitness 2006). However, much of this work is still speculative, and given the ancient imperatives of kin selection, it is likely that intergroup conflict will always constitute a challenge for scholars to fully understand, and for humankind to ameliorate.

whether a trait is socially desirable or not may be influenced by the role played by that trait in *multi-level selection*, with traits deemed desirable or eugenic having typically been the ones that were historically promoted during periods of intergroup competition and expansion via group selection. By contrast, traits that solely promote individual-level selection at the expense of group-level fitness, or pathologies that result from mutational accumulation, are the ones that are typically deemed to be undesirable and dysgenic.

Dysgenic Concerns

Michael A. Woodley of Menie

Introduction

The idea that certain patterns of fertility are dysgenic or eugenic is intimately coupled with normative considerations of social desirability. Further muddying the waters of this discussion are the ethical issues associated with the sorts of counteractive measures proposed by eugenicists to mitigate dysgenic concerns (i.e., sterilization, marriage licencing, financial incentives toward low or high fertility, etc.). Recent work has attempted to strip concepts like dysgenics and eugenics of their normativity by linking them (and their valancing in terms of social desirability) with multilevel selection, thus permitting these terms to be used objectively. This article will consider this recasting in detail before moving on to a discussion of whether patterns of fertility and other genetic changes actually justify dysgenic concerns historically.

Synonyms

Cacogenics; Genetic deterioration

Definition

Dysgenic concerns stem from the tendency for the genes underlying traits deemed *socially desirable* to decrease in prevalence as a consequence of selection pressures disfavoring their reproduction and the accumulation of mutations that degrade their function. In the West, the perception of

Review

Overview

The term *dysgenics* describes the tendency for the carriers of certain traits deemed socially undesirable to reproduce or otherwise proliferate to excess, and was first coined by Caleb Williams Saleeby (1913). This concept was expounded upon by Galton (1868), who identified three major classes of traits, high levels of which were considered to be socially desirable and necessary for the maintenance of civilization. Galton's three trait classes were *intellect*, *good character*, and *health*. To counter the

existential threat to civilization that Galton perceived to stem from the high fertility rates of those with low levels of these traits, a system of artificial selection known as *eugenics* (meaning good breeding) was proposed as a means of ensuring human betterment via the control of heredity.

Multilevel Selection

The idea that some traits (such as intelligence, altruism, etc.) are socially desirable is a value judgment; hence terms like dysgenic and eugenic are intrinsically normative and thus nonscientific, given that selection has no preferred direction in nature. Eugenic attributions of higher “fitness” to the carriers of traits like high intelligence (e.g., Lynn 2011) are no less problematic, especially given that the carriers of such traits seem to be at a fitness disadvantage in modern societies.

Recently however the case has been made that terms like eugenic and dysgenic might be empirically grounded when used as descriptors of the consequences of shifts in the relative strengths of individual vs. group selection in multilevel selection (Woodley and Figueredo 2013). High intelligence and altruistic disposition would seem to feed into group-level fitness, especially in the case of the sorts of unusual cognitive and personality combinations that characterize the *genius phenotype* – such individuals being capable of significantly increasing group-level fitness via *disruptive innovation* (e.g., innovations in cartography aiding colonization, engineering innovations aiding weapons manufacture, etc.) (Hamilton 2000). Consistent with this inference, despite having a large impact on group-level fitness, historical data indicate that geniuses typically fail to achieve replacement-level reproduction at the individual level (Simonton 2003). Another critical component of group-level fitness as it pertains to human populations is the presence of conditions that reduce the *relative fitness* of those exhibiting low levels of intelligence, poor social skills, etc., such as high extrinsic morbidity and mortality stemming from environmental (i.e., cold, famine, disease) and social (i.e., violence and warfare) harshness. Such conditions historically enhanced the relative fitness of those exhibiting higher intelligence,

lower time preferences, greater impulse control, and so on, facilitating the eventual *embourgeoisement* of Western populations via the downward social mobility of the elite reproductive surplus (Clark 2014). This would have simultaneously increased the probability that rare group-selected phenotypes will arise via population growth, who can further enhance this growth via their innovations (Hamilton 2000; Woodley and Figueredo 2013).

Conditions conducive to group selection prevailed throughout much of the West up until the nineteenth century, when reductions in the relative frequency and intensity of intergroup conflict diminished consistent with the period known as *Pax Britannica*, which spanned the nine decades from the end of the Napoleonic Wars to the First World War. Rising global temperatures coupled with advances in medicine and social innovations (such as welfare) released Western populations from many sources of ecological stress, which would have had the effect of reducing reproductive constraints on large segments of these populations. The rise of education and increased economic competition among individuals within Western populations would have furthermore imposed constraints on the relative fitness of the carriers of higher levels of intelligence and other bourgeoisie phenotype components, thus establishing gradients of dysgenic fertility with respect to these traits. This would have the effect of lowering the aggregate population levels of these traits with time (Lynn 2011; Woodley of Menie et al. 2018a).

Thus, when considered in terms of multilevel selection, the idea that certain patterns of fertility are objectively “good” or “bad” makes empirical sense, as fertility patterns can either *enhance* or *undermine* group-level fitness. The folk notion of social desirability therefore seems to be implicitly linked with considerations of cost-benefit trade-offs at the level of group fitness. Scrutiny of the writings of eugenicists from the early and mid-twentieth centuries indicates that they were cognizant of this, as they placed a premium on the promotion of traits clearly necessary for group selection such as selflessness and communal orientation, which they in turn saw as necessary for

the enhancement of society (Woodley and Figueredo 2013).

Coupled to alternating patterns of group- vs. individual-level selection is the idea of *mutation accumulation*, which results from the relaxation of purifying or mutation-eliminating selection on populations. The rate at which *de novo* mutations accrue in the germ lines of humans is around 100 per diploid genome per generation (Lynch 2016). The *mutation load paradox* postulates that such a rate of accumulation should lead to around 80% of the population failing to reproduce with reproductive surpluses among the remaining women of 16 or more children being necessary in order to ensure population viability (Kondrashov and Crow 1993). While reproductive failure and surplus of this magnitude are not observed among modern Western populations, pre-reproductive death and reproductive failure rates were and indeed still are extremely high (>50%) in premodern populations, likely because the negative pleiotropic impact of these mutations on aspects of cognition, personality, and health would have had higher fitness costs in the context of the harsher physical and social environments that characterized the West historically and still characterize much of what is termed the developing world today. The mutation load paradox can therefore be solved in part by stipulating that under modern conditions, the reduced fitness cost to having these mutations is permitting them to accumulate, which in turn is engendering subtle, cumulative fitness losses, both directly at the level of fertility and indirectly through their pleiotropic effects upon behavior (Lynch 2016, see quasi-empirical simulation in Woodley of Menie et al. 2018b), which may have implications for the maintenance of group-level fitness also. This is especially the case if some of these variants induce behavioral changes that significantly disturb group-selected cultural formations that engender fitness enhancing norms (Woodley of Menie et al. 2017a).

Actual Dysgenic Consequences

It has recently been found that selection operating on factors such as height, BMI, and age of menarche can produce meaningful changes in the

population means of these traits in just a handful of decades (Stearns et al. 2010).

The trait that has been most closely studied by those interested in dysgenics is intelligence. The *co-occurrence model* (Woodley and Figueredo 2013) posits that genetic selection and environmental enrichment have opposing effects on different variance components of intelligence, with selection effects being largest on the more heritable and more general intelligence (*g*)-loaded intelligence measures and the effects of the environment being largest on the less heritable and more specialized intelligence measures. Hence *g* may be declining in populations as a consequence of genetic selection, whereas specialized cognitive skills may be growing as a consequence of the Flynn effect (the secular increase in IQ of three points per decade). The growth in the latter is larger than the decline in the former; hence at the level of aggregate intelligence, IQ scores appear to be rising. Certain intelligence indicators may by virtue of very high or cross-temporally stable *g*-loading and high heritability, be declining nonetheless, when considered in isolation. Consistent with this dysgenic selection directly predicts the decline in usage frequencies of hard-to-learn vocabulary items across 100 years of sampling from a large textual corpus, even when controlling for rising literacy, word age, and serial autocorrelation effects. Usage of easy-to-learn words is increasing in frequency however in response to rising literacy, consistent with the Flynn effect (Woodley of Menie et al. 2015). A similar pattern has been noted in the case of digit span performance, where more highly *g* loaded working memory measures show signs of having declined over time, whereas the less *g* loaded short term memory measures show the opposite pattern (Wongupparaj et al. 2017). Parallel secular declines in factors such as processing speed, the per capita prevalence of macro-innovations and indicators of 'social intelligence', starting in the mid-nineteenth century, may also result from genetic selection on *g* (Woodley of Menie et al. 2017b). Consistent with this, it has been found that approximately 25% of the variance in the decline among these indicators can be predicted using polygenic scores that are predictive of both education

attainment and g and are declining over time in certain populations (Woodley of Menie et al. 2018a, see also Kong et al. 2017).

Concerning possible trends toward reduced *developmental stability* potentially resulting from mutation accumulation, Rühli and Henneberg (2013) list six medical abnormalities that have increased in prevalence throughout the twentieth century. There are parallel secular increases with respect to sinistrality (left-handedness) and certain measures of fluctuating asymmetry which may also track an underlying decline in developmental stability (Woodley of Menie et al. 2017b). It is also possible that the increase in the prevalence of neurodevelopmental disorders such as autism may, in part, be driven by mutation accumulation, although properly conducted longitudinal studies are required in practice to confidently make this inference (Lynch 2016).

Conclusion

Dysgenics can usefully be thought of as any genetic change, which either increases individual fitness or causes degradation of function, in both cases at the expense of group-level fitness. Dysgenics thus defined can be said to objectively correspond to a measurable negative outcome – i.e., reduced group-level fitness. The special emphasis placed on certain classes of trait historically by eugenicists, high levels of which have the potential to boost group-level fitness, suggests that folk notions of social desirability are intimately connected with the perceived costs and benefits of these traits to group-level fitness. This conceptualization also reduces the potential for *fact-value conflation*, as a pattern of fertility that has empirically deleterious consequences for group-level fitness, does not necessarily entail any particular course of *meliorational* political action – dysgenics in these instances simply becomes an empirical description of an objective phenomenon.

It is clear also that patterns of selection and mutation accumulation, starting in the mid-nineteenth century, may justify dysgenic concerns with respect to several traits.

Definition

Edward Osborne Wilson is an American biologist recognized as one of the foremost authorities on the study of ants. He is also widely considered as the father of sociobiology.

Introduction

Edward Osborne Wilson (born June 10, 1929) is an American entomologist, biologist, naturalist, and researcher. He graduated in biology at the University of Alabama, and, in 1956, he started to be part of Harvard University. In 1996, Wilson officially retired from the faculty of Harvard, but he continued to hold the seat of Professor Emeritus and Honorary Curator in Entomology. Edward O. Wilson is the author of books like *The Insect Societies* (1971), *Sociobiology: The New Syntheses* (1975), *On Human Nature* (1978),

The Ants (1990), and *The Diversity of Life* (1992). In this context, he is best known for studying *Sociobiology* and *Biodiversity* and for his relevant contributions in ecology – with the *Theory of Island Biogeography*. Moreover, Wilson is recognized for his biological specialty of the study of ants, what is called *myrmecology*.

Sociobiology

Wilson (1978) defines *Sociobiology* as the systematic study of social behavior focusing on biologic aspects. It is emphasized that this branch of knowledge covers all kinds of organisms, including humans. Regarding this, Wilson (1978) states that *Homo sapiens* is a species that exhibits a great genetic diversity that affects its behavior. Thus, for him, it will soon be possible to identify and locate specific genes that influence social behavior, even the most complex ones.

Moreover, it is relevant to say that the exposure of *Sociobiology*, brought by Wilson, instigated criticism from scientists, especially because the author includes the human species on his studies, along with the other animals. About it, Wilson (1976) affirms that it is possible to extend the sociobiological methods to humans, even if their behaviors are more complex and flexible. Beyond that, many social scientists do not recognize *Sociobiology* because they believe that culture has no genetic basis (Wilson 1978). However, the author exposes that geneticists have already

shown that several traits that affect social behavior have hereditary influence (Wilson 1978).

“Lord of Ants”

As previously stated, Edward O. Wilson is known for his studies on insects, focusing especially on ants. In 1990, Wilson and Hölldobler published the book titled *The Ants*, in which ideas such as the importance of the abovementioned species, its origin, its social behaviors, and the form of organization of its colonies are approached. In this sense, Wilson and Hölldobler (2005) assert that “ants are especially notable among the insects for their ecological dominance as predators, scavengers, and indirect herbivores” (p. 7411). Thus, the authors expose that the evolutionary history of the ants is relevant, since the ants demonstrate to have an extremely advanced social organization, besides the environmental influence at world levels (Wilson and Hölldobler 2005).

Biodiversity

According to Ehrlich and Wilson (1991), biodiversity studies refer to the systematization of all types of organisms, including the study of ways to preserve diversity and how it can be used for society’s benefit. In this sense, these authors affirm that the diversity of life can be considered a central theme on biology and that biodiversity studies “combine elements of evolutionary biology an ecology with those of applied biology and public policy” (Ehrlich and Wilson 1991, p. 758).

Regarding the progress of the knowledge about Earth’s biodiversity, over the past 250 years, Raven and Wilson (1992) explain that it has been rather slow because of the vast diversity on this planet – since it allows that many species live together in the same place (Wilson 1994). In this context, Wilson (1994) affirms that “the study of biodiversity is one of science’s greatest challenges, and humanity’s greatest needs” (p. 7). On the one hand, this enormous diversity shows itself as a source of wealth, promoting benefits for society – such as pharmaceuticals, petroleum substitutes, and other products useful to humanity

(Raven and Wilson 1992). However, on the other hand, all this biodiversity seems to be fading away at a rapid pace, mainly because of habitats’ destruction, deforestation, and pollution (Raven and Wilson 1992).

Concerning what has been previously stated, Wilson (1994) suggests that for thousands of years, human activity has been reducing the biodiversity of the Earth. To solve this problem, he says that the excessive growth of the human population must be controlled and proposes that each country should create a population’s control policy, calculating the ideal size of population for the preservation of biological wealth (Wilson 1994).

Island Biogeography Theory

In 1967, as a result from the partnership between Robert MacArthur and Edward Wilson, *The Theory of Island Biogeography* was published, representing a transition, in the context of ecology and biogeography, from studies with a descriptive perspective to studies with analytical approaches (Losos and Ricklefs 2010). In the first chapter of the aforementioned book, the authors highlight the relevance of an island as a study object, once it is the most appropriate unit for the beginning of scientific comprehension (MacArthur and Wilson 1967).

The authors understand insularity as a universal feature of biogeography, insofar the principles displayed in remote archipelagos apply in a certain degree to all natural habitats (MacArthur and Wilson 1967). Therefore, the purpose of *The Theory of Island Biogeography*, as stated by the authors, was to perform an examination of the possibility of a biogeography’s theory at the species level (MacArthur and Wilson 1967). The development of such theory took place by relating species distribution with population ecological concepts (MacArthur and Wilson 1967).

Among the contributions brought by the theory was a graphic which indicates the MacArthur-Wilson equilibrium model (Losos and Ricklefs 2010). Thus, the theory’s remarkable implication was that the biota of an island has a system by which species disappear, being replaced by new individuals at an equal proportion, assuming

a dynamic steady state (Losos and Ricklefs 2010). MacArthur and Wilson's development of ideas over ecology, population biology, evolution, and paleontology brought remarkable implications for conservation of species (Losos and Ricklefs 2010).

Biophilia

Biophilia is "the innate tendency to focus on life and lifelike processes," as defined by Edward O. Wilson, in his book *Biophilia*, published in 1984 (p. 1). Later, in the first chapter of his work, *The Biophilia Hypothesis*, Wilson (1993) explains the concept of biophilia, in other words but in the same sense, as "the innately emotional affiliation of human beings to other living organisms" (p. 31).

In fact, while developing the concept, Wilson (1993) explains that the term "innate" must be understood as "hereditary," as part of human nature. In this context, the author postulates that biophilia should be assimilated as a complex of learning rules able of being individually studied and should not be simplified as a single instinct. The author clarifies also that the emotions which surrounds the biophilia hypothesis, being defined by its learning rules, range from positive feelings to negative feelings or, as the author illustrates in his book: "from attraction to aversion, from awe to indifference, from peacefulness to fear-driven anxiety" (Wilson 1993, p. 31). It is possible to infer from this perspective that biophilia is based in learned behaviors which results from the fact we are connected to nature.

Thereby, Wilson (1993) concludes that when *Homo sapiens* separate themselves from the natural environment, interrupting his direct contact with nature, biophilic learning rules continue to influence strongly humanity over the generations. Biophilia, therefore, is expressed in the most diverse peculiarities of the new way of life artificially created by man (Wilson 1993). As the example brought by the author, it is interesting to observe how appealing attractions like zoos are for people all over the world.

It is also remarkable the influence biophilia has over humanity's cultural expressions. With the

development of language, the myths, for example, were created strongly affected by metaphors with living organisms (Wilson 1993). Myers and Saunders (2002) state that the various expressions of nature – such as plants, weather, landforms, and waters – represent something surpassing, singular, and remarkable for people's life. But above all those segments of the natural world, the most special case of human's biophilia is the experience with animals (Myers and Saunders 2002). The existence of a great quantity of pet owners all over the world proves the emotional connection humanity has with animals (Myers and Saunders 2002).

Wilson (1993), inquiring how biophilia's evolution could have happened, concludes that the likely answer is biocultural evolution or gene-culture coevolution. Therefore, the genes which determinate learning propensities were spread by natural selection, influencing the elaboration of culture (Wilson 1993).

In conclusion, defining himself as a conservationist, Wilson (1993) understands that biodiversity is at risk and, because of the disappearance of the living part of the environment, becomes necessary the development of a more sophisticated environmental ethic.

Conclusion

The undeniable relevance and admirable extent of E. O. Wilson's work make him one of the greatest scientists alive. He is considered a pioneer in important areas, as sociobiology and biogeography, having made remarkable contributions for the progress of science. He has been recognized by the scientific community, awarding many medals and prizes, among them, two Pulitzer Prizes. Furthermore, his work has a tremendous influence in the conservation movement; as an example, the E. O. Wilson Biodiversity Foundation is a nonprofit organization created to use education, technology, and business strategies to further the preservation of biodiversity. Being himself an advocate of the preservation of habitat and biodiversity of species, his work inspires people all over the world to join the cause.

Early Association Cue to Kinship in Primates

[Kin bias](#); [Kin recognition](#)

Definition

Kinship can be defined strictly as genetic relatedness above a certain threshold or broadly as describing genetic or social relatedness including

both consanguineal and affinal kinship. In primate research only the former is considered as “true” kinship, and the degree of relatedness is estimated based on a probabilistic proportion of shared genes. Due to the overlapping generation length in most primates, kin relations tend to consist of grandparent-parent-offspring relationships, sibships, half-sibships, and aunt-uncle-cousin relationships.

Kin recognition is the process of recognizing maternally or paternally related individuals. The mechanisms of kin recognition include direct genetic recognition via a cue, phenotype matching, and association-based learned recognition.

Introduction

Kin recognition is beneficial, even necessary: nepotism, kin-biased cooperation, mate choice, and parental behavior are all influenced by recognition of who is a relative. Most non-human primates (henceforth: primates) live in social groups, in which recognizing relatives from nonrelatives is highly relevant. There is ample evidence in primates for kin-biased behavior from preferential association to selective cooperation (Berman 2015). For example, kin are often the most preferred grooming partners and conflict allies. This indicates that primates indeed recognize at least their closest kin. How do they do that?

The mechanisms of kin recognition can be categorized as cue based and association based. The former are shown in species that use particular phenotypic features to recognize kin, such as cuticular hydrocarbon components in ants and odors in golden hamster’s scent-marking. Association-based recognition includes learning by imprinting and learned recognition due to close and consistent co-presence. Primates appear mainly to learn who is kin by associating with them (Rendall 2004). This is shown by cross-fostering studies and other experimental and observational studies that test whether interactions among unfamiliar relatives differ from those among unrelated individuals. They do not. For example, in captive monkeys raised in peer groups, separated from their mothers and other adults, social affiliation as adults is best predicted by early familiarity instead of paternal or maternal relatedness (Rendall 2004).

Maternal Kin Recognition

In most primates, males are the dispersing sex. Females remain in their natal group and, thus, associate with one another from birth. Such a system allows for the formation of matriline, in which maternally related females grow up in close association with their mothers, sisters, aunts, and even grandmothers. In many cercopithecines, matriline are the primary context in which cooperation and close association takes place: maternally related females are the most frequent and durable grooming and support partners. Maternal recognition in a matrilineal system is based on learning to know kin due to consistent and close co-presence, likely weighted by the type and frequency of interactions (Rendall 2004; Kapsalis 2004).

Matrilineal bonding does not determine behavior as strongly in certain other female philopatric species. Capuchins, for example, have less consistent tendencies to cooperate and associate with maternal kin despite female philopatry and strong affiliative bonds among females.

In species in which females disperse and males remain in their natal group, the dynamics of kin-based bonding are different. Now it is the males who remain in the natal group and may form brother-networks. In muriquis, which is a male philopatric species, maternally related males form cooperative bonds as adult, and juveniles seek to associate with their older brothers. However, maternally related brothers do not always prefer each other as partners. Similarly, in male chimpanzees, the strongest male-male bonds are not exclusively due to kinship (Mitani 2009). This may be due to maternally related (half-) brothers having a relatively large age-gap: adolescent and adult males rarely associate with their mother beyond reproductive age (with bonobos as a notable exception: Surbeck et al. 2011), which means that adult males do not spend time in association with their younger siblings who are still in mother's care.

Interestingly, primates can recognize maternal kinship also among their group members: They recognize group members' matriline membership, relative dominance rank, and mother-offspring relationship (e.g., Bergman et al. 2003).

Allocentric kin recognition is beneficial for successful navigation of a network of relationships characterized by kinship, friendship, and competition. For example, aggressive conflicts and their aftermath often involve opponents' relatives, who provide support, are targeted for redirected aggression, and may provide indirect reconciliation on behalf of their kin (e.g., Das 2000; Wittig et al. 2007).

Paternal Kin Recognition

Learning to recognize kin by association does not work equally reliably for paternal kin. When a single male fathers several offspring in one age cohort, age mates have a high likelihood of being paternal siblings. Age similarity thus may become a cue for kinship recognition among paternal siblings. However, recognizing kin by age similarity may nevertheless operate through familiarity, since half-sibs have formed peer relationships as juveniles. Age similarity is used for paternal kinship recognition in rhesus macaques and possibly also in baboons, where age-mate females and males have reduced likelihood of consortship (Widdig 2007).

Age similarity is an increasingly unreliable cue of kinship when multiple resident males have a possibility to father at least some of the offspring. Recent research is uncovering paternal kin recognition through other mechanisms. For example, rhesus macaques appear to use phenotypic matching of acoustic features to recognize their paternal kin (Pfefferle et al. 2014).

Conclusion

The most prevalent mechanism of recognizing relatives in primates is familiarity that is acquired through frequent association. This method is relatively crude and prone to lead to errors, yet it appears to provide a sufficient mechanism to identify relatives for the purposes of kin-biased cooperation, nepotism, and inbreeding avoidance in primates.

Definition

Conceptualized as an evolved behavioral system, attachment has been said to lead a “double life” such that it serves two complementary yet distinct functions: (1) to elicit proximity to and care from caregivers in infancy and childhood and (2) to

regulate the complex dynamics of adult pair-bonding and reproductive strategies (Chisholm 1996; Del Giudice 2009).

Introduction

The pioneering work of John Bowlby (1973, 1982) and his colleague, Mary Ainsworth (1964, 1989), along with more recent theoretical extensions and contributions by Belsky et al. (1991), Hazan and Shaver (1987), and others, forms the basis for attachment theory as it is understood today. This middle-level evolutionary theory is reflected universally in humans as a behavioral system that is initiated in infancy and persists throughout adulthood, aiming individuals toward greater inclusive fitness (i.e., successful passing of one's genes to the next generation) in the anticipated environment. Developmental considerations include: patterns of attachment as a marker of variation in life history strategies; early experiences with caregivers shaping initial patterns of attachment; the restructuring of attachment during middle childhood; and the influence of attachment on adult romantic relationships.

Attachment and Life History Strategies

Though Bowlby's attachment theory was based in Darwin's theory of adaptation, subsequent attachment research programs did not always emphasize its evolutionary roots. Belsky et al.'s (1991) evolutionary theory of socialization brought this basis back into focus. Building from Draper and Harpending's (1982) work, Belsky and colleagues proposed that developmental pathways toward adaptive reproductive strategies are initiated by experiences in childhood. In particular, Belsky and colleagues emphasized the first 5–7 years of life as providing important cues to the developing individual, including cues about the social context in which they live. These cues speak to the availability and trustworthiness of others and guide development toward life history strategies that optimize survival and reproduction given environmental demands. Life history strategies are comprised of suites of traits that influence how organisms allocate time and energy to competing

demands across the lifespan, including growth, mating, and parenting (Del Giudice 2014; Ellis et al. 2009). Harsh and unpredictable environments favor “fast” life history strategies characterized by early and unrestricted sexual activity, unstable interpersonal relationships, and early reproduction. Safe and predictable environments, on the other hand, tend to favor “slow” life history strategies and the opposite pattern of behaviors (Ellis et al. 2009). In addition to predicting individual differences in self-regulation, risk taking, and sexual behavior, variation in life history strategies is reflected in different patterns of attachment to caregivers and romantic partners (Belsky et al. 1991; Del Giudice 2014; Del Giudice and Belsky 2010). Thus, early interactions (i.e., between caregiver and child) influence developmental trajectories and life history strategies aimed at meeting ultimate goals. As such, attachment patterns constitute adaptive behavioral strategies that are contextually driven and serve the ultimate goals of survival and successful reproduction (Belsky et al. 1991; Chisholm 1996).

Early Attachment Experiences as the Foundation

The initial function of the attachment system during the first 5–7 years of life is to elicit proximity to and care from caregivers (e.g., mothers) during an extensive, vulnerable period of infancy and childhood. Humans are born quite immature and therefore are entirely dependent on their caregivers early in life. Thus attachment, as a behavioral system, equips infants with strategies that minimize mortality risk (Bowlby 1982). Attachment behaviors include signaling behaviors (e.g., smiling, cooing), aversive behaviors (e.g., crying, screaming), and active behaviors (e.g., clinging, following; Bowlby 1982). As children become more mobile, the caregiver serves as a secure base who can be returned to as needed during play and exploration (Ainsworth 1964, 1989).

The attachment behavioral system is conceptualized as reflecting the caregiving behavioral system such that once a child's attachment system is activated, it initiates the caregiver's

caregiving system (George and Solomon 1999). Various experiences, but particularly experiences of salient danger (either real or perceived), activate the attachment system and corresponding attachment behaviors (i.e., aversive and/or active behaviors). A child's enactment of attachment behaviors in response to threat or danger (e.g., crying and reaching toward the caregiver) serves to elicit caregiving behaviors (e.g., picking up, soothing, and protecting the child from harm). Both systems are subsequently deactivated once proximity between caregiver and child is achieved and the threat diminishes (George and Solomon 1999).

Building from Ainsworth's Strange Situation paradigm (i.e., an infant attachment assessment paradigm; Ainsworth 1964), early attachment measurements categorize a child's attachment pattern generally as secure, insecure, or disorganized. Insecure attachment patterns are further delineated into anxious/ambivalent and avoidant patterns of attachment. Each of these patterns is derived from the quality of repeated caregiver (un)responsiveness to the needs of the child. Caregiving quality is based on the accurate reading of and timely, sensitive response to a child's attachment behaviors (Belsky 1999). A caregiver's ability and willingness to provide quality care depend on a host of influences including the caregiver's own psychological attributes, health, social support, and reproductive strategies (Belsky 1999). Although bidirectional influences of mother and child characteristics (e.g., temperament) may contribute to the quality of interactions, attachment is formed in the presence of a power differential in the child-caregiver relationship (Belsky 1999). Accordingly, attachment is regarded as the close, emotional bond that the child forms toward the caregiver and not the reverse (Bowlby 1973, 1982).

Children of each attachment pattern (i.e., secure, anxious/ambivalent, avoidant, or disorganized) tend to display a corresponding set of attachment behaviors. Put simply, children with secure attachment patterns generally find their caregiver's ability and willingness to respond to

their needs predictable and thus engage more easily in normative exploration and learning opportunities (via the exploratory behavioral system). Children with anxious/ambivalent attachment patterns find their caregiver's ability and/or willingness to attend to their needs unpredictable and thus tend to be more clingy and demanding. This elevated behavior corresponds to hyperactivation of the attachment system (Mikulincer and Shaver 2012) which may serve to increase an unpredictable caregiver's proximity and responsiveness (Chisholm 1996). Children with avoidant attachment patterns find their caregiver to be unresponsive, harsh, and/or rejecting and therefore tend to withdraw and become self-reliant. This behavioral pattern corresponds to deactivation of the attachment system (Mikulincer and Shaver 2012) which may allow the child to maintain minimal proximity and avoid instigating harshness and/or rejection from a caregiver (Chisholm 1996). Finally, children classified as disorganized attach to their caregiver but not in a coherent, organized fashion. Disorganized attachment patterns are less frequently observed and most often associated with children who have experienced severe abuse or trauma. Associated behaviors include fluctuating (i.e., disorganized) use of avoidant and anxious behaviors, as well as freezing or trance-like responses to fear situations (Hesse 2016).

Dependency of attachment patterns on the quality of caregiving does not preclude variation in attachment among children in the same family. Caregivers may invest differentially in their children (i.e., favor one child over another) based on their own reproductive strategies (Trivers 1974), thus resulting in attachment variation among siblings. Additionally, some children may be more genetically predisposed to one pattern of attachment over another or may be more sensitive to environmental influences on development (i.e., differential susceptibility; Boyce and Ellis 2005), both of which contribute to individual differences in attachment even when receiving similar caregiving quality. Further, the intergenerational transmission of attachment and caregiving

behaviors is an area of research still not fully explored but may be an important piece in the puzzle (Belsky 1999).

During the early childhood period, attempts to identify sex differences in attachment patterns have generally been unsuccessful (Del Giudice and Belsky 2010). Given attachment during this early developmental period aims toward survival, sex-differentiated attachment patterns and associated behaviors may not be necessary until later developmental stages. In sum, it is the interplay between nature and nurture that guides early development of an individual's attachment system.

Hierarchical System of Attachment

While the term "caregiver" is used consistently here, the majority of attachment research programs (including Bowlby and Ainsworth's foundational work) emphasize the mother-child relationship. This focus is due to caregiving behaviors historically being carried out disproportionately by mothers (biological or otherwise) across cultural contexts. However, attachment is not limited to mother-child relationships (Belsky 1999; Bowlby 1973). Fathers, as well as additional caregivers (e.g., stepparents, family members, professional caregivers), are also included as attachment figures in what was described by Bowlby (1982) as a hierarchical system of attachment.

The primary caregiver is the individual who most frequently attends to the child's basic needs (often the mother). Additional caregivers with whom the child develops a close, emotional bond can hold a place in the attachment hierarchy as well. Placement within the infant attachment hierarchy may depend on frequency and quality of care and the strength of the child-caregiver emotional bond. Different patterns of attachment organization can develop between the child and individual caregivers as the types of interactions and quality of caregiving provided by each individual may differ (Howes and Spieker 2016). The development of multiple attachment relationships of varying attachment patterns is likely further complicated for children in foster care and

adoption systems where there may be increased inconsistencies (Howes and Spieker 2016).

Internal Working Models (IWMs)

Bowlby (1973) proposed that the early, recurring experiences a child has with a caregiver contribute to the child's IWM, a mental representation of the social world and him/herself in it. These IWMs allow for predictions about one's environment and support the capacity for goal-corrected behavior (i.e., the ability to adjust behavioral strategies based on the immediate context) in the attachment system. Specifically, one's IWM represents both (1) the child's expectation about the availability of caregivers (i.e., ability and willingness to provide care and love) and (2) the child's understanding about his/her worthiness of and ability to receive care and love. Children who developed secure attachment to their caregivers based on consistent, responsive caregiving develop IWMs of others as dependable, caring, and loving and of oneself as worthy of and able to be cared for and loved. Children with the opposite recurring experience (i.e., having developed an insecure attachment) generally develop IWMs of others as undependable and uncaring and of him/herself as unworthy of and/or unable to receive care and love. (Note that IWMs are more nuanced than explained here as they are based on a range of child-caregiver experiences and more specific attachment classifications.) Variations in recurrent experiences with multiple caregivers over time lead to more complex IWMs which are revised and updated throughout development. These IWMs become the filters through which relationships and interactions are initiated and interpreted and remain salient throughout the lifespan.

In sum, infants are equipped with an attachment system that functions to maintain proximity to caregivers during a vulnerable developmental period. Early attachment patterns are shaped by the quality of caregiving received and contribute to IWMs about oneself and others. These IWMs affect (and are affected by) subsequent attachment relationships and continue to be updated across development.

Attachment Is Restructured During Middle Childhood

Following the initial calibration of attachment and IWMs that takes place during infancy and early childhood, the attachment system is restructured during middle childhood. Middle childhood generally takes place between ages 6 and 11 (Colle and Del Giudice 2011; Del Giudice 2014). Although physical growth of the body is slowed during this developmental stage, middle childhood remains a time of profound change. In the brain, new neural connections proliferate (i.e., synaptogenesis), and white matter increases as neural circuits become functionally mature (Del Giudice 2014). These changes support increasingly sophisticated cognitive abilities, emotional competencies, and social behavior. During this time, children's social contexts are also rapidly changing. Relationships with peers take on increased importance as children no longer depend exclusively on their parents for survival (Del Giudice 2009). Intense social learning occurs as children play and begin to practice adult skills and behaviors (Del Giudice 2014). Important social challenges include learning to navigate peer dominance hierarchies, honing skills related to cooperation and competition, and forming stable friendships (Colle and Del Giudice 2011). Although not yet sexually mature, this period is characterized by a strong separation of gender roles, as segregation into same-sex peer groups peaks prior to adolescence (Colle and Del Giudice 2011; Del Giudice 2014).

Adrenarche as a Developmental Switch Point

Also known as "adrenal puberty," adrenarche is the hormonal event that signals the transition to middle childhood (Del Giudice 2009, 2014; Del Giudice and Belsky 2010). Between ages 6 and 8, glands in the adrenal cortex begin to release increasing amounts of adrenal androgens into the bloodstream (Del Giudice 2009; Del Giudice and Belsky 2010). On average, boys and girls begin adrenarche around the same time; however, there is variation in when individual children experience this event (Del Giudice 2014). The timing of adrenarche may be accelerated or delayed based

on cues to harshness or support in the early childhood environment, including the availability and quality of parental care and levels of marital conflict (Ellis and Essex 2007). Children who begin adrenarche relatively early (or late) tend to begin puberty similarly early (or late; Del Giudice 2014).

Although adrenal androgens do not produce many visible bodily changes, they exert powerful effects on brain development and function (Del Giudice 2014; Del Giudice and Belsky 2010). However, the brain's response to adrenal androgens may differ for boys and girls. Adrenal androgens can be converted into estrogen or testosterone in the brain, sending brain development and function down sexually differentiated pathways (Del Giudice 2014; Del Giudice and Belsky 2010). Indeed, middle childhood is characterized by emerging sex differences in affect regulation, responses to stress, aggression, and conduct problems (Del Giudice 2009; Del Giudice and Belsky 2010).

Still years away from attaining sexual and reproductive maturity, differences between boys' and girls' "prereproductive" behavior and relationship patterns become evident during middle childhood, with adrenal androgens likely playing a key role (Del Giudice 2009). Adrenarche may be responsible for the onset of romantic and sexual attractions around ages 7–10 (Del Giudice 2009). Further, hormonal changes during this phase may induce, and provide a biological basis for, emerging sex differences in attachment (Del Giudice 2009).

Some researchers consider adrenarche to be a critical switch point in the development of sex-differentiated life history strategies, including patterns of attachment. According to Del Giudice (2014), a "developmental switch" is a hormonally driven regulatory mechanism that "turns on" at a specific point in development (or during a sensitive period). Such a mechanism is posited to integrate information from an organism's physical and social environments with information about their current state to guide developmental trajectories toward strategies that promote survival and reproduction under these conditions (Del Giudice 2014; Ellis 2013). Developmental switch points

are likely critical in the context-dependent development of alternative (fast vs. slow) life history strategies and their associated behavioral patterns.

Emergence of Sex Differences in Attachment

Relative to earlier developmental stages, an individual's fitness becomes less dependent on parental care and investment during middle childhood. As such, the attachment system can prepare to take on more mature functions, including directing pair-bonding and reproductive activities (Del Giudice and Belsky 2010). Middle childhood thus serves as a critical transition period between attachment system functioning during infancy and adulthood, leading to a partial reorganization of attachment patterns initially calibrated in response to early caregiving (Del Giudice 2009). According to the "psychobiological hypothesis," this hormonally mediated recalibration of the attachment system co-occurs with adrenarche (around age 7) and results in sex-differentiated patterns of attachment (Del Giudice and Belsky 2010). Unlike infants who face largely similar survival-related challenges regardless of biological sex, an evolutionary framework predicts sex-based differences in adult attachment because men and women have recurrently faced different mating-related challenges throughout human history (Del Giudice and Belsky 2010). Therefore, it is posited that sex differences in attachment emerge during middle childhood to prepare individuals to adopt reproductive strategies that are most likely to optimize fitness for members of their biological sex in adulthood (Del Giudice and Belsky 2010).

Specifically, males and females are expected to develop different patterns of insecure attachment in environments characterized by moderate levels of stress or danger (Del Giudice 2009). Early stress and insecure attachment should favor reproductive strategies that prioritize mating (over parenting) effort and early reproduction. Under these conditions, males with insecure attachment should adopt avoidant strategies to facilitate successful intra-sexual competition and attraction of multiple sexual partners. Whereas avoidant attachment among boys may be characterized by increases in aggression, externalizing behaviors, and inflated self-

esteem (integral to seeking and attaining status among same-sex peers), in men such patterns may display as low commitment to romantic relationships and increased promiscuity (Del Giudice and Belsky 2010).

Females with insecure attachment, on the other hand, should adopt anxious/ambivalent attachment patterns within moderately stressful environments. Such care-eliciting strategies may function to maintain closeness to a mate (particularly an avoidant one) and to maximize the amount of investment received within that partnership (Del Giudice 2009). Whereas girls with anxious attachment may demonstrate passivity and internalizing symptoms, as women they may display increased impulsivity, early and unrestrained sexual behavior, and a strong desire for intimate and committed relationships with men (Del Giudice and Belsky 2010). However, females may adopt more avoidant interpersonal orientations within extremely harsh or dangerous environments (Del Giudice 2009).

Research suggests that the predicted sex differences in insecure attachment emerge during middle childhood. Unlike studies of infants and younger children, studies of children ages 7–11 reveal consistent sex differences in insecure attachment patterns on attachment questionnaires and doll-play tasks (although not on attachment interviews that focus on past experiences with caregivers). In research revealing sex differences in insecure attachment, boys are more likely to display avoidant (vs. anxious/ambivalent) attachment, whereas girls' attachment is more likely to be categorized as anxious/ambivalent (Del Giudice 2009; Del Giudice and Belsky 2010). Relatively few studies have tested for sex differences in attachment in middle and late childhood; however, this pattern has been revealed in research conducted in the United States, Canada, Israel, and Italy (Del Giudice 2009).

The sex-dependent distribution of insecure attachment in middle childhood is consistent with patterns of romantic attachment observed among men and women in adulthood (Del Giudice and Belsky 2010). This suggests that information used to calibrate sex-differentiated attachment patterns at adrenarche may carry over

to the next developmental switch point at gonadarche (i.e., the transition to adolescence), providing an opportunity to further adjust reproductive strategies and attachment before achieving reproductive maturity (Del Giudice 2014; Ellis 2013).

The Role of Paternal Caregiving

Evolutionary developmental models emphasize the importance of parental behavior in transmitting information to children regarding levels of environmental harshness and support (Belsky et al. 1991). However, mothers and fathers may shape the behavioral and reproductive strategies of their children in qualitatively different ways. For instance, unlike maternal investment, paternal investment levels reflect the amount of male-male competition, character of the mating system, and availability of paternal care within the local environment (Del Giudice 2009; Draper and Harpending 1982). On this view, low paternal investment (including father absence) suggests to offspring that their environment is relatively polygynous, pair-bonds do not last, and men preferentially allocate resources toward attracting multiple mating opportunities at the expense of investing in offspring (Ellis 2004). Sons and daughters are posited to use this information to guide their development and behavior in different ways. For instance, low paternal investment is expected to promote increased aggression and hypermasculinity among sons to promote successful intrasexual competition, and early sexual development and short-term sexual relationships among daughters (Del Giudice 2009). Consistent with this view, research demonstrates unique effects of fathering quality in shaping daughters' pubertal timing, with high-quality paternal investment predicting delayed sexual development among daughters (Ellis 2004). Further, research by Chisholm et al. (2005) has shown that women growing up without their father in the home experience earlier menarche and first birth and are more likely to be insecurely attached than other women. This research suggests that when monogamy is not perceived to be the norm (such as in contexts characterized by low paternal investment), insecure attachment patterns can facilitate women enacting fast reproductive strategies, even

if they retain a preference for long-term commitment (as may be the case with anxiously attached women; Del Giudice 2009).

In sum, middle childhood is a critical transitional period between a survival- (and caregiver-) focused attachment system calibrated in early childhood and the mature attachment system that regulates mating behavior in adolescence and adulthood (see section "[Romantic Attachment in Adolescence and Adulthood](#)"). Insecure attachment patterns become sex-differentiated at a hormonally mediated switch point, as boys and girls develop patterns of attachment that promote successful intrasexual competition and reproduction in moderately stressful environments. Consistent with this view, the sex-biased distribution of insecure attachment that emerges during middle childhood is consistent with patterns of insecure romantic attachment observed among adult men and women.

Romantic Attachment in Adolescence and Adulthood

As noted, the mature function of the attachment system in adolescence and adulthood is aimed toward regulating the complex dynamics of adult pair-bonding and reproductive strategies (Chisholm 1996; Del Giudice 2009). Bowlby (1982) conceptualized the attachment system as persisting throughout the lifespan, and Ainsworth (1989) proposed sexual pair-bonding as among the types of attachment relationships beyond infancy. Hazan and Shaver (1987) were the first to fully explore romantic relationships as an attachment process. In their empirical studies of adult romantic attachment, they found that the attachment patterns of child-caregiver relationships present similarly in adult romantic relationships and that romantic attachment patterns correspond to IWMs of self and others. It is important to note, however, that their study was less conclusive regarding the relation between retrospective reports of early attachment and current romantic attachment patterns in adulthood. This lack of clarity has been the source of ongoing discussion and research regarding aspects of

continuity and change in attachment across the lifespan, which is considered next.

Continuity and Change

The attachment system evolves across development in ways that exhibit both continuity and change. While there are enduring aspects of attachment for which early childhood is the foundation, important differences also emerge as the function of attachment shifts toward an emphasis on pair-bonding and reproduction (Del Giudice 2009). As argued by Figueredo et al. (2009), adult romantic attachment relationships likely require different behavioral approaches as they serve different primary purposes (i.e., reproduction) than child-caregiver attachment relationships (i.e., care and protection). Hence, attachment behaviors evident in childhood (i.e., signaling, aversive, and active behaviors) may be facultative in that they are specific strategies aimed at solving the problems of an extended, vulnerable childhood (Figueredo et al. 2009). Attachment patterns in adulthood, on the other hand, correspond to an increased complexity in the attachment hierarchy which becomes multidimensional beginning in adolescence. In addition, romantic attachment patterns should be sexually dimorphic given different reproductive pressures facing males and females (see section “[Emergence of Sex Differences in Attachment](#)”; Del Giudice and Belsky 2010).

Adult pair-bonding involves coordination of three behavioral systems: attachment, caregiving, and reproductive (Ainsworth 1989). Adult romantic attachment serves in part to increase reproductive fitness by increasing paternity certainty (e.g., limiting the likelihood that a father invests fully in offspring that are not his), allowing for shared parental investment during an extended period of child dependency, and therefore increasing the likelihood of thriving offspring (Zeifman and Hazan 2016). While the emphasis here is on the ultimate goal of reproduction, the romantic attachment system may also continue to serve survival purposes for humans, a vulnerable, ground-living species (Zeifman and Hazan 2016). In this sense, maintaining proximity to a caring, dependable partner is useful in times of threat (such as intense illness). Unlike childhood,

adult attachment and caregiving roles are interchangeable between partners.

Continued Shifts in Attachment During Adolescence

Adolescence is the transition from childhood to adulthood (i.e., roughly ages 10–19 years) and, as such, involves developmental processes that guide behavior toward increased autonomy and decreased dependence on caregivers. According to Del Giudice (2009), adolescence allows for childhood influences from caregivers (e.g., attachment) to be modified and replaced as one transitions into adulthood. This is evident in changes to the attachment hierarchy that continues in adolescence.

The attachment hierarchy in adolescence evolves through a process of expansion and revision. This evolution is considered in the Important People Interview (IPI; Rosenthal and Kobak 2010). Peers are central to the daily experience of adolescents and, in many cases, become more accessible and knowledgeable about the dilemmas experienced by the adolescent (Rosenthal and Kobak 2010). This results in increased support-seeking and affiliative behaviors among peers which provide the backdrop for the potential formation of peer attachment relationships (i.e., enduring bonds with peers who are sought out in times of danger or threat; Rosenthal and Kobak 2010). Additionally, increased social interactions of mixed-gender peer groups (as opposed to more prominent same-sex peer groups in childhood) and the emergence of dating behaviors likewise set the stage for the formation of romantic pair-bonds (Ainsworth 1989). Romantic attachment becomes increasingly prominent during the transition into adulthood, as the reproductive behavioral system becomes more salient at the onset of puberty.

The attachment hierarchy can also be revised as adolescents mature. While childhood caregivers (i.e., parents) often remain primary attachment figures (Rosenthal and Kobak 2010), the attachment relationship itself may shift. One initiator of hierarchy revision is the developmental shift toward autonomy. In response to this shift, the goal-corrected partnership (i.e., caregiver and adolescent) may renegotiate the balance between

responsive caregiving and promoting autonomy and increased self-reliance (Allen and Tan 2016). Further, maturing metacognitive functions provide an opportunity for adolescents to reevaluate their caregiver attachment relationships in a process of resolution. In this process, adolescents are able to see their caregivers in both positive and negative lights. This “deidealization” of caregivers allows an adolescent to reevaluate and revise not only their attachment hierarchy and behaviors but also, importantly, their IWMs (Allen and Tan 2016). This is particularly important for adolescents who had negative early attachment experiences (i.e., insecure attachment with caregivers). For those unable to resolve IWMs, establishing healthy friendships and forming enduring bonds are difficult (Allen and Tan 2016).

Overall, attachment in adolescence has potential for both continuity and change. The role of the caregiver as a secure base is often maintained, though there is a developmental shift toward increased autonomous exploration. In addition, attachment hierarchies and corresponding IWMs are open to expansion and revision as additional bonds are formed with friends and romantic partners and as mature metacognitive functions allow for resolution of negative early attachment experiences.

Measurement of Romantic Attachment and IWM

Adult romantic attachment is considered a “person by situation” construct such that it can be activated differentially based on the attachment relationship and the specific context (Mikulincer and Shaver 2012). On the one hand, attachment can be thought of as self-sustaining such that individuals both approach and interpret relationships from the perspective of their IWMs, which then become validated. On the other hand, adult romantic attachment relationships in particular are dynamic, and the context can be complex. An attachment pattern with one partner in a particular social context may not mirror that with a different partner and/or different social context (Mikulincer and Shaver 2012). Additionally, individual and environmental factors such as heritable dispositions and the local sex ratio impact reproductive

strategies and, thus, the attachment system (Del Giudice 2009). In this sense, romantic attachment in adulthood reflects a complex biopsychosocial process.

Initial measurements of adult attachment focused on patterns established in infancy under the premise that early attachment experiences serve as the foundation for attachment behaviors and IWMs in adulthood. The Adult Attachment Interview (AAI; Hesse 2016) focuses on retrospective self-reports of early attachment relationships and the coherence of those relationships based on “states of mind” (i.e., IWMs). These comprehensive interviews channel individuals’ organized attachment patterns into the three categories (i.e., secure-autonomous, insecure-dismissing, and insecure-preoccupied) which closely align with descriptions of their early childhood attachment pattern counterparts (i.e., secure, avoidant, and anxious/ambivalent, respectively). For individuals not able to be categorized (i.e., their attachment behaviors are not observed in an organized pattern), the categories of “unresolved/disorganized” and “cannot classify” were added subsequently. As conceptualized by Bowlby (1973, 1982), attachment later in life is subject to subsequent interactions and experiences and therefore does not remain static. Thus, the AAI opened the door for relationship researchers to consider ways to assess the complexity and multidimensionality of adult attachment patterns.

To measure adult romantic attachment, Hazan and Shaver (1987) developed a forced-choice, three category (i.e., secure, anxious/ambivalent, avoidant) measure. Though these categories are reminiscent of infant attachment patterns, the questionnaire included both retrospective reports of early attachment as well as a recent romantic attachment relationship and current IWMs. As interest in romantic attachment gained momentum among relationship researchers, measurement of this construct continued to evolve. One measurement trend conceptualized romantic attachment as two dimensional, such as in Griffin and Bartholomew’s (1994) Relationship Styles Questionnaire (RSQ). Based on earlier versions, the RSQ is a 30-item inventory that considers two dimensions: IWM of self and IWM of others.

Individuals fall into four possible categories (i.e., secure, preoccupied, fearful-avoidant, and dismissing-avoidant) based on a positive/negative classification on both dimensions. The Experiences in Close Relationships Scale (ECR: Brennan et al. 1998) is another such 36-item measure which considers attachment along two dimensions. In the ECR, individuals are categorized based on their scores on avoidance and anxiety scales, and individuals scoring low on both scales are classified as having a secure attachment style. Updated versions of the adult romantic attachment measurements mentioned support current romantic relationship research as well as research using a life history framework (Chisholm et al. 2005).

Conclusion

The theory of attachment, as originally developed by Bowlby and elaborated on in the seminal works of Ainsworth and others, has been integrated into a modern life history framework (Belsky et al. 1991; Del Giudice 2009). Early parent-child attachment relationships (e.g., secure vs. insecure) are central to life history models of the development of alternative reproductive strategies. Adolescent and adult romantic attachment relationships are also theoretically relevant to life history models, and increasing efforts have been made to incorporate attachment patterns during these later developmental periods into a life history framework. In particular, modern evolutionary developmental research integrating attachment theory and life history theory elucidates the role of emergent sex differences in attachment as mediating sex differences in reproductive strategies.

Definition

Early childhood and adolescence are stages of human development that precede adulthood and are bridged by a juvenile period.

Introduction

Evolutionary developmental psychology (EDP) applies the principles of evolutionary biology to understand human developmental norms and variability (Del Giudice and Ellis 2016). On this view, stages of human development (and their characteristic physiological, cognitive, and behavioral patterns) have been shaped by natural and sexual selection throughout the history of our species. This perspective emphasizes the interactional influences of environmental and genetic factors in shaping individual developmental pathways. Accordingly, an understanding of early childhood and adolescence requires consideration of (1) the role of past, current, and future expected environments in guiding development; (2) functional phenotypic plasticity that occurs in response to varying environmental conditions; and (3) behavioral outcomes that are adaptive in context yet may be labeled “maladaptive” from other perspectives.

Early Childhood

Early childhood (considered here as the first 5–7 years of life) is a period of considerable somatic growth and brain development and, as such, of high energy demand. Trade-offs must be made when allocating limited energetic resources to the competing needs of brain, body, and reproductive development, particularly within deprived environments (Bjorklund and Ellis 2014). For example, in impoverished conditions, preservation of vital organs (e.g., the brain) may be favored over other somatic growth. This allocation pattern can improve immediate survival outcomes but increase one’s likelihood of developing metabolic syndrome within food-abundant adult environments (thrifty phenotype hypothesis; Hales and Barker 2001). Thus, early childhood is not only an important time of discovery and play for the purpose of stimulating critical social and cognitive skills. This period also has long-term implications for an individual’s developmental trajectory that can impact their adult phenotype and fitness-relevant outcomes

(Bjorklund and Ellis 2014). The ability to receive multiple reliable cues (i.e., information) from the physical and social environment during early childhood is therefore imperative.

Harshness and unpredictability are unique and fundamental dimensions of the environment to which children are sensitive that influence development of life history strategies and promote associated suites of behaviors and preferences (Ellis et al. 2009). Environmental harshness refers to extrinsic (uncontrollable) factors that increase one’s risk of disability or death. Salient proximate indicators include local exposures to violence and premature death. Environmental unpredictability refers to high variability in local morbidity-mortality rates and is reflected by frequent changes in residence, parental figures, and socioeconomic conditions (Ellis et al. 2009). Together, cues of harshness/unpredictability communicate information to developing individuals regarding their likelihood of a long life given the social and energetic resources available in their local ecology. As such, presence (or absence) of these cues direct individual development toward relatively fast (or slow) life history strategies, which serve to match one’s phenotype to his/her expected environment.

Infants enter the world already having received environmental harshness/unpredictability information from maternal hormones that pass through the placenta and help calibrate the naïve stress response system (Bjorklund and Ellis 2014). Once delivered from the womb, the infant enters a physical and social environment that is host to a multitude of novel stimuli (e.g., hormones in mother’s milk; touch during caregiver interactions). Many of these stimuli have, over generations, served as reliable cues to anticipated environments (i.e., the environment expected in adulthood) ranging in harshness/unpredictability and warmth/supportiveness. During childhood, the majority of such cues are provided by the behavior of caregivers.

According to Belsky and colleagues (1991), experiences in early childhood provide critical information regarding the availability of social resources (e.g., the ability to trust others and maintain enduring relationships). The development of

attachment to one's parents may reflect a child's earliest cues regarding the degree to which trusting and enduring relationships can be expected. Specifically, secure and insecure (anxious/avoidant) attachments are expected to develop in response to high and low levels of parental investment, respectively. Children often develop secure attachment when they receive consistently high levels of sensitivity, availability, and emotional warmth from the parent(s). Insecure attachment, on the other hand, reflects inconsistent and/or low levels of such relationship qualities (Belsky et al. 1991). These contrasting forms of attachment likewise correspond to the continuum of possible life history strategies, with relatively fast strategies developing in response to an anticipated environment that is characterized by heightened competition for scarce resources and minimal parental investment in offspring (Belsky et al. 1991; Bjorklund and Ellis 2014). Within this context, individuals who demonstrate high impulsivity, aggression, and opportunistic interpersonal orientations may enjoy better fitness outcomes than individuals whose developmental trajectories did not prepare them for such conditions. Consistent with this view, evidence suggests that aversive early life interactions and experiences (e.g., rejecting and/or inconsistent parenting) predict behaviors indicative of faster life history strategies, including earlier sexual debut and first reproduction (Bjorklund and Ellis 2014).

In sum, early development is sensitive to multiple reliable cues that forecast the environments that children will inhabit as adults. These cues (e.g., hormones from maternal milk, parent-child attachment) guide developmental trajectories in ways that function to match individual phenotypes to their expected future environment and promote instantiation of life history strategies along the slow-to-fast continuum. However, it is important to note that the extent to which an individual is influenced by the myriad stimuli to which they are exposed in early childhood may critically depend upon their level of differential susceptibility to context (Belsky et al. 1991; Bjorklund and Ellis 2014). That is, some individuals may be more (or less) attuned to specific environmental cues, elucidating why we can observe striking differences in outcomes among

individuals from similar backgrounds (including children from the same family).

The Juvenile Transition and Adolescence

Following early childhood is a period of juvenility ("middle childhood"; approximately ages 7–11) that precedes adolescence. Middle childhood is characterized by the onset of adrenarche (involving secretion of adrenal androgens), appearance of adult molars (enabling independent foraging for food), decreased dependency on parents, brain maturation, and increased social play and learning (Hochberg and Belsky 2013). Sex differences in attachment also emerge during this time. Importantly, this is a period of slowed growth in humans, which serves as a distinct contrast with adolescence.

Adolescence is a uniquely human stage of development that generally takes place between ages 11 and 17 (Hochberg and Belsky 2013). This stage is largely defined by puberty-specific changes, including gonadal maturation and a rapid growth spurt in height and weight, and broadly entails physiological, behavioral, and motivational changes that prepare males and females for adult social roles and reproductive activities (Ellis et al. 2012; Hochberg and Belsky 2013). Although parental investment often continues into early adulthood, the influence of parents decreases during adolescence, as the importance of peer relationships simultaneously increases. Other puberty-specific changes include maturation of primary and secondary sex characteristics, shifts in sleep patterns, increased caloric intake, and increased sensation seeking (Ellis et al. 2012). As sexual motivation and competition increase in intensity, adolescents begin to assess their desirability as mates, form mating-relevant preferences, and practice mate attraction tactics (Ellis et al. 2012). From the perspective of EDP, strong selection has historically occurred during adolescence due to the implications of competition for fitness-relevant resources (including mates and social status). As such, adolescents experience pronounced emotional and behavioral responses to their social successes and failures (Ellis et al. 2012).

From an evolutionary viewpoint, developmental trajectories functionally vary in response to environmental conditions. Adolescence is no exception. Adolescence is posited to be a sensitive period for change that is regulated by hormonal switches (Ellis et al. 2012). In addition to heritable variation, the timing (and duration) of puberty is susceptible to the influence of individuals' physical and social environments (e.g., family stress; Hochberg and Belsky 2013). Accelerated maturation serves as a component of a fast life history strategy that is adaptive under harsh/unpredictable conditions. Specifically, accelerating the transition from juvenility to adolescence (and adolescence to adulthood) under stressful conditions may increase one's probability of reproducing before death, especially for girls (although this transition may be delayed when access to calories is inadequate; Hochberg and Belsky 2013). Under conditions of harshness/unpredictability, taking risks that jeopardize long-term health and well-being may provide better immediate outcomes than "playing it safe."

Importantly, functional sex differences in morphology and behavior manifest during this period. Adolescent boys achieve fertility approximately 2 years after their growth spurt begins (around ages 14–15). However, they appear juvenile in terms of their body hair, stature, muscularity, and voice. As such, adolescent males are able to learn adult social roles while sexually mature, but not yet seen as competition by more dominant adult males (Hochberg and Belsky 2013). During pubertal maturation, testosterone activates courtship behavior and increases social dominance among boys (Ellis et al. 2012; Hochberg and Belsky 2013). Adolescent boys may enact a variety of behavioral strategies to gain social status and mating opportunities, including physical aggression (e.g., bullying; Hawley 2011). In addition, boys' engagement in potentially hazardous risk behaviors (e.g., fighting, reckless driving) increases during this time, with potential implications for fitness. Indeed, male risk-taking increases when being viewed by same-sex peers of similar status or after viewing images of attractive females (Ellis et al. 2012). From a fitness perspective, males have more to gain and less to

lose (relative to females) by engaging in risky behaviors, and research suggests that such strategies are effective. For instance, bullies often begin dating at a younger age than their same-sex peers, and social status achieved by adolescent boys can persist into adulthood (Ellis et al. 2012).

Girls achieve menarche approximately 1 year after their peak growth in height (Hochberg and Belsky 2013). In contrast to males, adolescent females appear feminine and show signs of sexual maturity (e.g., subcutaneous fat deposits in their thighs, buttocks, breasts), which can aid in mate attraction (Hochberg and Belsky 2013). However, human females remain infertile until approximately age 18, when ovulation reaches adult frequency and the birth canal achieves adult size. This gap between menarche and reproductive competence allows girls to learn adult social roles and practice mating skills without conceiving (Hochberg and Belsky 2011). As noted earlier, environmental factors may affect the pace at which girls reach these development milestones (and promote associated life history traits). For instance, the timing of female pubertal maturation is influenced by early environmental conditions, including exposure to family disruption/father absence (Hawley 2011). Girls are posited to encode father absence (or low-quality fathering) as suggesting that male investment in reproduction is not likely to be available when one reaches reproductive age. Under such conditions, girls can increase their reproductive success by accelerating maturation and engaging in earlier sexual activity, getting pregnant earlier, and having multiple short-term relationships (Hawley 2011). Under more supportive and benign conditions, however, a relatively late transition to adolescence allows for greater preadolescent growth, which can increase somatic, social, and psychological capacity for girls (favoring future over current reproductive success; Hochberg and Belsky 2013).

Conclusion

When considering variability in adult outcomes, one must look back to experiences

during early childhood and adolescence to see the full picture. It is here that evolutionary psychology takes a developmental approach. During early childhood and adolescence, individuals receive proximal cues (e.g., through parent-child interactions or family transitions) that interact with more distal cues and genetic factors to shape developmental trajectories in functional ways.

These changes function to match the individual to their anticipated future environment. While plasticity (the capacity for change) in some domains may persist into adulthood, childhood and adolescence constitute sensitive periods for structuring brain, body, and reproductive development via hormonal switch points (Bjorklund and Ellis 2014). As such, what happens during these stages can have long-term implications, and adult outcomes viewed as “maladaptive” from a societal perspective may reflect an individual “making the best of a bad situation” when confronted with circumstances that are less than ideal (Ellis et al. 2012).

Definition

Pre-Darwinian concepts of “species”.

Introduction

The attempt to partition a continuous evolutionary process into discrete units is the essence of the “species problem,” the unresolved question of *what*, if anything, “species” are. Modern (here

defined as post-Darwinian) definitions of species comprise upwards of 30 distinct concepts (Zachos 2016) emphasizing different diagnostic biological features. “Species,” however, was not an exclusively biological concept until around the nineteenth century; it has a long philosophical history with roots in Platonic and Aristotelian thinking. Here, two types of species definitions are traced from their philosophical origins to Darwin’s time: first, conceptions of the species *category* or *rank* (i.e., the entire class of units known as species), and second, early approaches to defining species *taxa* (specific units within the category, e.g., *Homo sapiens* or *Cavia porcellus*). The latter, in particular, has been the subject of recent debate, with scholarly approaches falling into two camps: the conventional “essentialists” and the “non-essentialists.” Finally, the impact of Darwin’s work on species definitions is examined to conclude he did not necessarily revolutionize taxonomy, as is often assumed, but rather altered the analytical framework in which it was conducted and interpreted.

Application of the Concept

The concept of “species” did not have a purely biological meaning for much of its history. The idea of definable types or categories of biological and nonbiological entities alike stretches back to antiquity, with the most well-known works being Plato’s *Theory of Forms* and Aristotle’s *Categories*. Plato and Aristotle sought, in the broadest terms, to classify things by defining their “essences,” and Aristotle referred to “eidos” (species) in both his biological and logical works. Aristotelian philosophy formed the bedrock of much Medieval thought, and “species” continued to be applied to classify biological and nonbiological things alike. According to Wilkins (2009), the first definition of “species” in a specifically biological context was published in 1686 by an English naturalist, John Ray. It remained routinely used to classify nonliving objects until the nineteenth century, however: indeed, Linnaeus classified minerals alongside plants and animals in his *Systema Naturae*.

Defining the Species Category

The term “species” has at least two meanings: species *taxa*, and the species *category* to which all species taxa belong. Definitions of species taxa are applied to discern discrete groups in nature, so they describe the boundaries between these groups; the species category, on the other hand, is a rank in the taxonomic hierarchy and therefore outlines the characteristics species taxa share that mark them as members of the category.

“Species,” in the category sense, was a relative term in classical and early modern scholarship, unlike the fixed rank it occupies today. This is best illustrated by what became known in the Middle Ages as *Porphyry’s tree* (Fig. 1), a scale of classification by the third-century Greek neoplatonist philosopher Porphyry. The tree is a nested classificatory hierarchy of dichotomous divisions where all levels (except the highest and lowest) are “genus” to the level below it and all levels are “species” to that above it. By contrast, the species category occupied an absolute rank in Linnaeus’ *Systema Naturae*, first published in 1735. His taxonomic hierarchy comprised five levels, with species occupying the lowest; this system is still in use today with additional ranks above and below the species level.

Defining Species Taxa

More than 30 definitions of species taxa are in use today (Zachos 2016), but despite this diversity they are all based on what Mayr (1959) has called “populationist” thinking. This approach is characterized by a belief that the “type” (the average) “is an abstraction and that only variation is real” (p. 2, *ibid.*). The traditional interpretation of the history species taxa definitions is a clear dichotomy with Darwin at the center: before him the standard approach to classification was essentialism, and he revolutionized taxonomy by pioneering population thinking. In the essentialist or “typological” (Mayr 1959) approach, species are conceived of as Platonic types with necessary and sufficient properties that defined them. Thus, the “type,” defined by properties that must always be present,

Early Definitions of Species,

Fig. 1 Explanatory text: Porphyry's tree, with a classification of humans to illustrate its use. Each level of classification is "genus" to the level below it and "species" to the level above it, except for the highest and lowest levels, which are the summum genus and infirma species, respectively. Classification proceeds dichotomously: each genus is split up into species according to a "differentia" with two options. (Adapted from Fig. 2.1 in Zachos 2016)

is real, and variations around it are illusions. The established view holds that the stranglehold of essentialism produced “two thousand years of stasis” (Hull 1965), principally because it does not allow the essential characters to vary in a population while evolution by natural selection requires them to.

This view has been increasingly successfully challenged. The essence of criticisms is as follows:

1. The practice of pre-Darwinian taxonomy was not restricted to an essentialist paradigm (even if taxonomists adhered to an essentialist worldview in theory).
2. Essentialism was not the sole theoretical approach to taxonomy, and other species taxon concepts emphasizing genealogy rather than essential defining features were in use before Darwin.

Regarding the first point, Winsor (2003) makes the case that the pre-Darwinian practice of classifying organisms more frequently followed a polythetic approach in which species were delineated

according to common but not *essential* shared features. She describes two widely applied approaches. “Chaining” involved acknowledging the continuity of features between groups in nature: “each species or genus was linked to the next by clear similarities, but by the end of the chain all the characters of the first link had been lost” (p. 392). The method of “exemplars” defined groups with reference to a “typical” member, analogous in some ways to today’s type specimens in taxonomy; potential members of the group were then compared to the typical member and excluded if they were distinct enough. Even if early taxonomists theoretically conceived of species in an essentialist paradigm, this did not necessarily inform the practice of classifying organisms. Instead, classification was largely pragmatic and taxonomists acknowledged problematic “fuzzy boundaries” between groups in nature.

That is not to say that an essentialist theoretical conception of species was universal, however. Wilkins (2009) claims a “generative” conception of species, which emphasized common descent rather than the need to exhibit essential and

sufficient features, was actually the most commonly used species taxa definition. There are numerous examples to support his case, including the first species definition in a purely biological context by John Ray (“...No matter what variations...if they spring from the seed of one and the same, they are accidental variations” (Ray 1686 quoted in Zachos 2016) and Kant’s (1775) assertion that “In the animal kingdom the division of nature into... species is grounded on the general law of reproduction” (p. 11). Regarding Linnaeus, commonly conceived of as the archetypical essentialist, Richards (2010) writes that “if he was an essentialist, it was of a genealogical kind. Essences were passed on in reproduction via the transmission of medullar matter...” (p. 58). There were, of course, pre-Darwinian theoretical essentialists alongside those who prioritized descent, but the variety of early species concepts has been severely underestimated in the traditional account.

Darwin’s Contribution

In the traditional view, Darwin liberated biology from the shackles of essentialism by promoting “population thinking.” It is clear that this narrative lacks support in the reevaluated interpretation. Indeed, Darwin never produced a clear species definition and his view on species remains debated (Zachos 2016). His fundamental impact, instead, lies in the overarching philosophical framework in which taxonomy was interpreted: the relationships between organisms classified in the pre-Darwinian Linnaean system are now understood in terms of shared descent.

Conclusion

“Species” referred to living and nonliving entities for much of the history of the concept. Biologically speaking, “species” refers to at least two concepts: the species category and the species taxon. The species category was a relative term in classificatory hierarchies in classical and early modern scholarship, but occupied a fixed rank

from the publication of Linnaeus’ *Systema Naturae* onwards. The traditional view with regard to early definitions of the species taxon is that Platonic essentialism dominated taxonomic theory and practice until Darwin pioneered population thinking, but this view is increasingly challenged. The established view, at the very least, underestimates the variety of species definitions in use in pre-Darwinian times; a shared feature of many early species definitions emphasizes shared descent and genealogy. It is likely that many early taxonomists employed more pragmatic definitions in the actual practice of classifying organisms. In light of this reinterpretation, Darwin’s contribution to species definitions is not so much that he revolutionized taxonomy, but rather that he altered the fundamental framework in which species were interpreted.

Early Perspectives on Evolutionary Change

Definition

The idea of evolution existed in the writings of various philosophers and scientists for many centuries before Charles Darwin produced a formal theory consistent with a large body of scientific evidence.

Introduction

Though Charles Darwin is the individual most closely associated with evolutionary theory

in the public imagination, evolutionary perspectives on the origin of life had been a topic of discussion among philosophers and scientists for millennia. Among the pre-Socratic Greek philosophers, for example, Anaximander of Miletus (c. 610-546 B.C.E.) thought that the first animals were aquatic, with land-dwelling forms developing later. The first terrestrial ancestors of modern humans were amphibious, according to Anaximander, born in water and spending only part of their lives on land. Empedocles (c. 490-430 B.C.E.) speculated further that new species arose accidentally from the disjointed parts of deceased animals, mixing and intermingling in new configurations. When the new combinations were well-suited to their environments, those survived to breed and became new species.

Classical Greek Perspectives

Plato and Aristotle both wrote about the origin of species as well, though they went in a different direction than the pre-Socratics. Plato argued that the Creator (Demiurge, in Plato's terminology) created the world in a complete and perfect form, with all conceivable forms of life already present, because if any of them were missing, the world would be incomplete; thus, the creation would be less than perfect, as would be its Creator as well. Aristotle, Plato's student, expanded on this view by proposing that all species were created to occupy a particular place, as a step in a *Scala Naturae*, or Ladder of Nature, later also commonly referred to as the Great Chain of Being. Like most ladders, the Ladder of Nature has a top and a bottom, and Aristotle proposed that organisms are arranged hierarchically, so that the world contains both higher and lower forms of life. This idea would remain influential all the way up to Darwin's time.

Early Christian Perspectives

The early Christian thinkers in Rome, most notably the fourth-century bishop Augustine of

Hippo, also speculated on the possibility of evolutionary change, in ways that might surprise modern readers. In Augustine's book *The Literal Meaning of Genesis*, he taught that worshipers should not take the Biblical account of creation literally but rather that living things were not created in a state of final perfection. Instead, they were made in a state of potentiality, and they transform slowly over time. In keeping with Aristotle's ladder, these changes involve development toward higher forms, but only the angels and the human soul were already perfect and in their final form at the moment of creation. Augustine also allows that the many species of insects, worms, and other small animals not mentioned in the Bible were not created by God on the fifth and sixth day, but rather emerged on their own through spontaneous generation from rotting organic matter. This idea was quite influential; well into the nineteenth century, it was widely believed that maggots emerge spontaneously from spoiled meat, for example.

Post-Roman Islamic Perspectives

Following the fall of the Roman Empire, the Greek and Roman philosophical and scientific traditions were interrupted for a number of centuries, but Islamic scholars continued to consider evolutionary ideas. Ibn Khaldun, in his *Muqaddimah* (1377), for example, speculates that humans developed from other primates, including monkeys, through a process by which species became more numerous. Well-acquainted with Aristotle, Ibn Khaldun reiterates the idea of a Great Chain in which species are arranged hierarchically as lower and higher forms, but he also asserts that some forms change into others, in an ongoing and endless process.

The Medieval Period

In the Early Middle Ages, as the works of Aristotle and Plato were reintroduced into the European universities, religious scholars like Peter Abelard and St. Thomas Aquinas made

Aristotle a centerpiece of their speculations on the natural world. Aquinas in particular held Aristotle in such reverence that when he cited him as a source, he referred to him simply as "The Philosopher," as no further identifying information was needed. The medieval view of biology is simply an updating of the Great Chain of Being, in which species occupy a hierarchical ranking in a perfect creation, with hell at the bottom of the ladder and God at the top. In a perfect hierarchy, there are no gaps and no unfilled positions, and thus there is no way that an organism would alter its position and therefore no evolutionary change. Although this perspective would greatly influence the eventual rise of seventeenth- and eighteenth-century biology, Aquinas was actually open to the possibility of evolution. Like Augustine before him, he cautioned that the account in Genesis should not be taken literally, or at least not in way that conflicted with what natural philosophers (scientists) were learning about the natural world. Aquinas argued that there is no necessary conflict between the idea of a divinely created universe and the concept that, via natural processes, it may have changed over time.

Eighteenth-Century Science

Although the idea of a fixed hierarchy of species remained influential for centuries, in the eighteenth century, several influential philosophers began to question it again. In France, Georges-Louis Leclerc, Comte de Buffon, wrote that modern species were modifications of earlier forms, changed by environmental factors. He used cats as an example, suggesting that leopards, tigers, and domestic cats plainly share a common ancestor. Buffon speculated that the approximately 200 species of mammal known at the time were actually modifications of only 38 original animal forms. This idea was quite influential in European scientific circles, unfortunately, so was Buffon's idea that those earlier forms had arisen through spontaneous generation. His fellow Frenchman, Denis Diderot, also wrote that living things arise through spontaneous generation,

though he added an early attempt at describing natural selection: new forms are spontaneously generated all the time, and they either survive or fail to survive based on how well-suited they are to their environment, by a process of trial and error.

Meanwhile, in England, James Burnett wrote in 1792 (perhaps borrowing from Ibn Khaldun) that man had descended from other primates and that over long periods of time, species would change their characteristics in response to changes in their environment. He gave no indication of what processes might be involved in such change, however.

Into the Nineteenth Century: Erasmus Darwin and Jean-Baptiste Lamarck

In the late eighteenth and early nineteenth century, Erasmus Darwin, Charles Darwin's grandfather, also wrote about the origins of life in a remarkably prescient manner. In *Zoonomia* (1796), he speculated that all warm-blooded mammals must have a common ancestor in the distant past. In his best-known work, the epic poem *The Temple of Nature* (1802), Erasmus Darwin writes that this common ancestor of all animals must have originated in the sea, and he does so in verse (*Canto I*):

Ere Time began, from flaming Chaos hurl'd
 Rose the bright spheres which form the circling
 world;
 Earths from each sun with quick explosions
 burst,
 And second planets issued from the first.
 Then, whilst the sea at their coeval birth,
 Surge over surge, involv'd the shoreless earth;
 Nurs'd by warm sun-beams in primeval caves
 Organic Life began beneath the waves.

Shortly after the publication of Erasmus Darwin's epic, the less-poetic Jean-Baptiste Lamarck became the best-known evolutionary theorist prior to Charles Darwin with the 1809 publication of *Philosophie Zoologique*, in which he introduced the influential notion of the *inheritance of acquired characteristics*. Lamarck dispensed with the idea of a common ancestor, instead following Buffon and Diderot's notion

that new life forms are continuously emerging via spontaneous generation. These new species then adapt to their environment by changing their use of their organs and muscles in response to environmental pressures, and they then pass along these structural changes in their own bodies to their offspring. A Lamarckian explanation of the giraffe's long neck, for example, would focus on the idea that during its life, a giraffe had to stretch frequently to reach leaves, and because of this stretching, its offspring will inherit a slightly longer neck. The inheritance of acquired characteristics became widely known as Lamarckism, and it influenced subsequent discussions of evolution, including Darwin's own deliberations on his data, throughout the nineteenth and into the twentieth century.

One last pre-Darwinian theorist deserves mention here: Robert Chambers, whose best-known work, *Vestiges of the Natural History of Creation* (1844), was published anonymously, with the author's identity only confirmed posthumously, when the eighth edition was published in 1884. The book was quite popular with the public but widely derided by the scientific community for its simultaneous embrace of both the latest scientific findings and a distinctly unscientific religious notion of predestination. Chambers acknowledged that the fossil record clearly reveals evolutionary change over time, but this change follows a progressive, ascending path that leads inevitably, inexorably to man at the top of the Great Chain of Being. In this view, natural processes do operate on the development of species, but only as part of a preordained master plan that leads to humanity as the highest organism. *Vestiges* was extremely popular; both Abraham Lincoln and Queen Victoria are known to have read it, along with Alfred Lord Tennyson, Elizabeth Barrett Browning, and William Gladstone. The book stirred up so much controversy and was so reviled by members of the Royal Society that its publication is frequently cited as one of the reasons that Darwin chose to delay the publication of *On the Origin of Species* for another 15 years, lest his own work receive the same contemptuous dismissal by the scientific community.

Definition

Apoptosis	Distinct form of cell death that reflects a highly regulated sequence of physiological events
Axons	Principal means of sending signals from the neurons

Dendrites	Major sites for receiving inputs from other neurons
Fetal	Week 9–week 40 gestation
Necrotic cell death	Pathological process that follows insult or injury to a population of cells
Neonatal	1–28 days living
Neurons	Specialized nerve cells that communicate with one another using electrical and chemical signals
Infant	1 month–12 months living

Introduction

The human brain develops in a predictable sequence but not at an even pace. Early experience during the postnatal period undergoes processes that underlie plasticity and capacity for adaptation in brain development. The human brain will double in size in the first year with the prefrontal cortex being the last brain area to mature. The prefrontal cortex houses our most advanced cognitive functions such as attention, motivation, and goal-directed behavior. Human brain development involves gene expression and environmental influence. Genes begin the process of brain development, and experience furthers the process. Development of the human brain remains incomplete until the age of 25.

Early Stage of Brain Development at Birth

A neonatal brain must first undergo development within the prenatal stage in utero. The neural tube is the first well-defined neural structure within the brain. The neural tube will eventually form the ventricular system of the brain. The structural and functional identity of the sensory and motor cortices remain malleable to the effects of input and experience into early postnatal development. Most neurodevelopmental events involve the proliferation of neural elements (Stiles and Jernigan 2010). Most neuron production takes place on the walls of the ventricles during brain development. The brain has almost all the neurons it ever will at birth, and most neurons are still immature that

connections between neurons are weak or have not yet been formed. They possess the characteristics of post-mitotic cells; once formed, they are no longer capable of dividing and producing new cells. Neurons need to become a part of the information processing networks and do so by developing axons and dendrites to communicate with other neurons. Synapses allow for the transmission of electrochemical information essential to communication in the brain by passing messages between neurons. Early in the postnatal period, the number of synapses plateau at levels nearly 200% as observed in the adult brain and form at a faster rate than at any other time between the ages of birth and 3. According to the neurotrophic hypothesis, neurons that establish effective connections are able to obtain more neurotrophic factor and are more likely to survive. There are two processes that involve a substantial loss of neural elements. A normal loss of 50% or more of the neurons within a brain will be due to a natural occurrence of cell death. Natural cell death occurs mostly in the prenatal period, whereas pruning occurs in large scales in the postnatal period. Necrotic cell death is a mechanism for eliminating damaged tissue from the biological system. Apoptosis is a cell-intrinsic process ultimately resulting in the breakdown of DNA and supports proteins and fragmentation of the cell. Apoptosis can reach up to 70% in some regions across the cortex and peaks during prenatal life. A systematic elimination of up to 50% of connections following a large scale of excess production occurs as a result of pruning. Microscopically, rapid formation and retraction of connections of individual neurons over time periods of minutes or hours can be observed. Cell death and pruning play essential roles in establishing complex networks of the developing brain. Important to cell death in brain development is the role played in regulating the establishment of effective and functional neural circuits. Substantial evidence has shown that cell death plays an essential role in eliminating cell populations that serve only a transient function in brain development (Stiles and Jernigan 2010). Proliferation and migration of glial progenitors (specifically oligodendrocyte progenitor cells (OPC)) continue for a protracted

period. Unlike neural progenitors, glial progenitors continue to proliferate as they migrate. OPC begins to differentiate by extending processes and increasing myelin protein expression. They synthesize a number of trophic factors that appear to contribute to the maintenance of axonal integrity and neuronal survival. Newer evidence has suggested that a subset of the OPCs dispersed throughout the brain form excitatory and inhibitory connections with neurons, potentially contributing actively and directly to neural signaling (Stiles and Jernigan 2010). Early in the postnatal period, transient connections form throughout the brain, which are unobservable in adults.

Experience in Brain Development

During the postnatal period, the mature organization of the neocortex emerges over a protracted time and requires diverse forms of input via all of the major sensory systems (Stiles and Jernigan 2010). The specific experience of the organism plays an essential role. Alternative patterns of brain organization will emerge when input specific aspects are lacking. Greenough's "experience expectant" and "experience dependent" offer constructs for the importance of early postnatal input. Enrichment and deprivation can alter input and have dramatic effects on structural and functional organization on the developing brain. Environmental changes influence neonatal behavior after birth which enables continuity between prenatal and postnatal behavior (Satnojevic et al. 2012).

Conclusion

The early events in the prenatal period provide an initial pattern that is underspecified and malleable. The mature human brain has a characteristic pattern of folds and ridges. This enfolding is thought to be an adaptation to the dramatic growth of its size during the course of evolution. Brains do not develop normally in the absence of critical genetic signaling or of essential environmental input (Stiles and Jernigan 2010). The regularity of developmental processes of the brain follows genetic, factored constraints.

The developmental process relies on the right neural elements presenting at their appropriate developmental time.

Early Theories of Language

Demetra Themistocleous and Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

[Darwin's theory on language evolution](#); [Muller's theories on language evolution](#); [Origin of language](#)

Definition

The early theories of language refer to the early theories addressing the evolution of language.

Introduction

The origin of language in the human species is a topic that has received increased attention over the

centuries. Due to the scarce evidence, there are difficulties in studying how language emerged. Therefore, researchers who wish to study the emergence of language need to draw inferences from other kinds of evidence such as historic petrified and physical remains and studies of language acquisition and evaluate the differences between human language and systems of communication existing among other animals.

On the 8th of March 1866, the Linguistic Society of Paris prohibited any existing or future discussions on the topic, and this ban continued its legacy in the West until the late of the twentieth century (Stam 1976). The absence of empirical evidence has led many researchers to consider the entire subject as inappropriate for further research examination. In our days several theories address the evolution of language (Tallerman and Gibson 2012). Many scholars in the field of linguistics, psychology, anthropology, and others have endeavored to explain the commencement of language in the early 1990s (Christiansen and Kirby 2003). It is of paramount importance, however, to consider the contribution of early theorists, such as Friedrich Max Müller and Charles Darwin, whose legacy was significant to further research in language acquisition in later years.

Friedrich Max Müller and His Early Theories on the Evolution of Language

Müller was a German philologist who proposed some early theoretical formulations concerning the origins of language. After the publication of *The Origin* in 1859, Müller was fascinated of the idea of human evolution. The tradition of giving disparage names to the theories regarding how language evolved commenced by him, and this was an important factor in his campaign against Darwin's evolutionary theory. Müller (1877) established associations between Darwin's evolution on humans and many other ideas about development, and he concluded that languages are subjected to historical radical change. However, he later realized that he underestimated Darwin's arguments and his suggestions concerning the history of human evolution. In 1864, Müller

presented his *Lectures on the Science of Language*. In this period of time, he started to reevaluate Darwin's theory. In his book "The Descent," Darwin had a section about Language, in which he proposed his own theories about the evolution of language. Müller had different ideas about how language emerged, and therefore, he talked in public about "Mr. Darwin's Philosophy of Language" in 1873 (Knoll 1986).

In these talks, Müller suggested that the language faculties of humans are distinguished from other creations; therefore it was impossible that the human development evolved from a lower form without language acquisition. His point of view was supported by his opinion that the linguistic roots are considered the original building blocks of language. In his *Lectures on the Science of Language*, he proposes that Indo-European verbal communication had developed from hundreds of verbal "cells." Müller hypothesized these linguistic roots as fundamental of the theory of mind. He assumed that they establish the principles for the Kantian intellectual classifications used by the mind to establish cognizance out of raw sense of perception. This capacity of the individual's mental structure separated man from animals since it formed the basis of man's exclusive capacity to form a concept and think rationally. Without these capacities, neither language nor thought was possible. Müller concluded that because animals do not have this intellectual structure, their evolution into humans was impossible (Müller 1877). In 1861, Max Müller published a list of theoretical concepts concerning the origins of language. He later abandoned most of his theories which include the bow-wow theory, the pooh-pooh theory, the ding-dong theory, the yo-he-ho theory, and the ta-ta theory.

Bow-Wow Theory

The overall idea of the bow-wow theory is that the beginning of language can be linked to the era when the progenitors begun to mimic the sounds in their natural environment, a process called "onomatopoeia." The natural world was of paramount importance in the origination of language since the sounds of animals played a significant role in the invention of the vocabulary used in

verbal communication. On the one hand, Thorndike (1943) was doubtful about the credibility of this theory as the beginning of language. On the other hand, recent studies support that being able to mimic sounds in the natural environment was of paramount importance in the evolution of language (Malle 2002).

A major drawback of this theory is the fact that people use different words to describe the sounds of animals according to their country and more specifically due to their language. For instance, the sound of a pig can be translated differently across the countries. In English a pig makes the sound "oink-oink," and in Russian it makes the sound "hyru-hyru," while in Chinese it makes the sound "oh-ee-oh-ee." Therefore, the sound and pronunciation of the words are not similar among the different languages. Another challenge is that there are few onomatopoeic words in the languages worldwide. In case the theory was credible, then it should have plenty of words out from the basic rule of onomatopoeia. The hypothesis that language is determined by how a person interprets a sound was rejected, since there are many languages and nobody can suggest that human vocabulary arose from these sounds (Thorndike 1943).

Ding-Dong Theory

The idea behind the ding-dong theory is sound symbolism which is a nonarbitrary connection between phonetic features of linguistic items and their meanings. Max Müller proposed the ding-dong theory by stating that meaning comes from sounds. According to this hypothesis, the origin of language emerged evolutionary with the names our ancestors gave to objects, activities, and natural occurrences after an identifiable sound associated with it in real life (Mandavilli 2016). An important characteristic of this notion is the fact that words having high front vowels were used to name small or jagged objects in comparison to words having round vowel which were used to name large or round-shaped objects. It is suggested that people used sound symbolism to give meaning to words through onomatopoeia, which is the formation of a word by the imitation of a sound made by or associated with its

referent in real space and time. “Boom,” for example, was the word given for explosion (Mitchell et al. 2013).

A major drawback of this theory is that onomatopoeic words are not the same in every country because the sound and pronunciation of the words are not similar among the different languages. People in different nations used their onomatopoeic words which are formed in regard to how they interpret different sounds. These words are a very limited part of their vocabulary since many ideas such as love, hate, harmony, and the sea do not make any noise. Thus, the relationship between meaning and sound is not established by any convincing evidence. For this reason, this theory was later abandoned by Max Müller (1877).

Pooh-Pooh Theory

The early speculative language theory of pooh-pooh refers to the notion that language emerged from unintentional vocal responses to agony, fright, astonishment, enthusiasm, satisfaction, or other emotions (Barber 1965). Although animals produce sounds as well, language is unique only to humans. “Ouch!,” “Aaah!,” and “Wow!” are some examples of the unintentional vocal responses that emerged from this hypothesis. This theory can be found in the literature as “the expressive theory,” “*the interjectionist theory*,” or “the expressions of emotions theory” (Barber 1965). Max Müller supported the pooh-pooh theory for a while, but later he abandoned it (Müller 1877).

The notion of the pooh-pooh theory that language has many emotional exclamations has been widely criticized by many reviewers. It has been argued that the explanations provided by this theory constitute a very limited part of the vocabulary of different languages. Further, the various languages worldwide have different interjections. For instance, in English pain is “ouch,” while in Greek it is “aou.” Therefore, it is indicated that sounds could have been different if their origin was from interjections. To conclude, although early human beings could use words based on interjections, these may have been ultimately overruled by more sophisticated and abstract

terms (Mandavilli 2016). Finally, it is important to emphasize that although animals react to the sudden feelings they experience using sounds, they didn’t develop language as human beings did.

Ta-Ta Theory

According to Richard Paget, who was specialized in speech science and the origin of speech, the ta-ta hypothesis supported that speech and the development of sound was produced to endorse the hand and body movements of the individual. So as to better demonstrate the meaning behind the gestures, these sounds developed different words or combinations of sounds unavoidably leading to speech patterns (Paget 1930). For instance, when a person would say ta-ta, he was basically saying good-bye with his tongue. At some point, this theory was even supported by Charles Darwin (Mandavilli 2016). In the literature, there are several theories such as the oral gesture theory and the chew-chew theory that support the idea that the origin of language begun from early human gestures made from their mouth. It is of paramount importance, though, to understand that it is not feasible to explain the origin of some words using the ta-ta theory.

A major drawback of this early theory on the origins of language is the fact that in order for people to be able to communicate between them, they must see each other in person. Also, there must be daylight, or firelight, and with nothing blocking one’s view. In the case of hand gestures, it is important that hands are free from doing something else (Crowell Meir et al. 2010). Last but not least, in order for this hypothesis to be the origination of communication, it required a number of gestures be in place already for humans to imitate with their mouth gestures, but it didn’t explain how these gestures arose in the first place.

Yo-He-Ho Theory

Verbal communication commenced as growls, moans, and rhythmic chants which occur from the overwrought efforts of ancient menfolk to move a boulder or heave a rock, as it is suggested by the yo-he-ho theory (Mandavilli 2016). Every

time these people were working hard to move something heavy, they produced a sound which slowly developed into words such as “heave” and “lift.” Therefore, if they didn’t want to memorize their favorite growl-sound and use it over and over again, this sound would seem to be random. However, these growls would not be accounted as words in a lingual meaning since they would seem unlikely to fall into consonant-vowel patterns (Rice 1976). The yo-he-ho theory does, however, have a benefit since it is responsible for the inducement, the cause, and the aim of the language. It describes language as emerging from a need to communicate and for making the engagement among men possible in organized activity, rather than seeing language resulting from a cave dweller imitating an animal’s howl to assist him while he was away for his dinner (Barber 1965). The yo-he-ho theory can be found in the literature as “yo-heave-ho theory” and “Social interaction source,” all of them proposed that the origin of speech begun as growls and moans (Mandavilli 2016).

Notwithstanding the above, evolution plays an important role since it claims that human society developed gradually because men began thinking of new things to do and began doing them collectively. What makes this theory interesting, however, is the query of what motivates the speechless cavemen move a boulder in the first place since language emerged from the growls and moans of their teamwork. Unfortunately, the origin of grammatical structure is not explained or how a social system got started void of language (Rice 1976).

To summarize, it is a matter of fact that language is a human trait. All efforts to explain how language emerged have failed because of the absence of knowledge concerning the origin of any language. An important factor for the inability to acknowledge the origin of language is because none of the animals possesses any transitional form of communication. As a consequence, Müller could not differentiate between humans’ linguistic faculties and the growls or sounds of animals. Also, the cultural roots of various hand gestures did not suggest verbal communication. Last but not least, most of his theories did not explain the origination of different ideas or things

that do not produce any sound, and this resulted to a limited vocabulary of the languages. As a result, there could not be an explanation of the origin of names of such concepts, if his theories were chosen as the origin of language.

Charles Darwin’ Work on the Origin of Language

In his book, *Origin of Species*, Darwin intentionally did not refer to human evolution in detail (Darwin 1859). Although it was perceived that this was a mere oversight, this was not true. Darwin carefully avoided to thoroughly refer to his hypothesis on human evolution because he knew that his theory would not be accepted, but rather it would probably provoke the existing insurmountable opposition. His rivals, however, emphasized the importance of human mind, and language in particular, to compete Darwin’s work. Müller, one of the reputed scholars of that time whose work on evolution of language was summarized above, was considered as Darwin’s most intimidating rival on the linguistic front (Stam 1976). In 1861, Müller delivered lectures at the Royal Institution of Great Britain. These lectures, entitled as “*Lectures on the science of language*,” were published soon afterward, and Müller used his expertise in the “*science of language*” as a strong weapon to attack Darwin and Darwinism (Müller 1861). Müller’s hypothesis about the origin of human language in relation to how animals communicate provoked Darwin to further study language.

In 1871, Darwin published his second book *The Descent of Man and Selection in Relation to Sex*. In this book he raised the subject of human evolution, and he provided explanation of how language emerged. Darwin’s “*musical protolanguage*” model was a response to this propaganda and thus represented a combination of comparative data, evolutionary insight, and a biological perspective on language. His innovative view of language and his models are still astonishingly applicable to contemporary arguments. Darwin proposed a complex model to explain the evolution of language in which he recognized

the necessity of various mechanisms in order to produce vocal sounds. Most importantly, he observed that several components in vocal learning shared many biological capacities similar to birds in the production of sound.

Further, Darwin took advantage of a wide comparative collection of data, by using his insight of both nonhuman primate behavior and vertebrates. He proposed a broader theory of evolution that is applicable to insects, flowers, and birds. His purpose was to reveal through investigation general ideas, like sexual selection and shifts of function, to give more information about common and unique human characteristics. Darwin's model suggested that language emerged only to humans since there is no progression of function between nonhuman primate calls and language (Fitch 2006).

Language as a Natural Aptitude

In his book *The Descent of Man and Selection in Relation to Sex*, Darwin discusses about the evolution of human mind. He suggested that animals have feelings, attention, memory, and many other mental traits in common with human beings (p. 34–52). Some of his opponents, however, and specifically Müller had already suggested the hypothesis that animals have memory, experience feelings, and so on. What was of paramount importance, however, was the subtitle “Language” (p. 53) in his book where he spoke for the first time about the evolution of language.

Theoretically, Darwin made some significant observations. First, he acknowledged the essential difference between the biological ability that enables humans to acquire language and specific languages (like Latin or English). Although he initially suggested language as an instinctive propensity shared by all humans, he later emphasized that language is not an instinct provided that every language has to be learnt. He suggested language as natural aptitude whose expression implies that both biological and environmental preconditions must be satisfied.

Second, in spite of the fact he was cognizant of the unique characteristics of the human vocal tract, Darwin supported that the human ability for language must be sought in the brain, rather

than the peripheral vocal tract. He concedes that a unique characteristic of humans is the ability to speak fluently and coherently by controlled movements of their lips and tongue (p. 59). Nonetheless he repudiates that simple power of articulation is enough to distinguish human language, since as he explained parrots can talk as well. It is further stated that it is not speech but humans who are largely capable of joining certain sounds with particular concepts that is definitive of language. This capacity apparently depends on the development of the mental abilities.

Finally, Darwin argued that there is a coherence of the evolution of language to the birdsong, which he thought it was similar to human language. Both humans and birds have fully instinctive calls that they have to learn. Also, he emphasized the fact that both birdsongs and speech form regional dialect depending on their place of residence.

The Musical Protolanguage Model

Darwin's model of the evolutionary development of the language capacity assumes that various features of language were obtained in specific order, inspired by unique selection pressures. The hypothetical arrangement that was classified by each addition was called as protolanguages (Hewes 1973). Darwin firstly hypothesized that the evolution of humans progress from an ape-like ancestor to the protohuman cognition. He proposed that some primates developed highly mental capacities even before any form of verbal expression come into use (p. 57). He also stated that both social and technological factors act as drivers of this superior cognitive ability.

Darwin later proposed the musical protolanguage model (Fitch 2006), after observing numerous resemblances in birdsong and human language. He precisely implies that there is an inherent ability to replicate vocals evolved analogously in humans as well as songbirds to express feelings such as love, jealousy, and success. He reasoned that sexual selection is mainly used as the main driver behind the evolution of spoken language.

What is crucial for further investigation, however, is the transition of the musical

protolanguage model to a meaningful speech. According to Mithen (2005), the progress of the musical protolanguage model to a meaningful speech remains the greatest explanatory challenge for all musical protolanguage theories. Darwin, however, referred to Müller's writings, and he embraced the theory that language emerged from natural sounds, such as the imitation of the sounds of animals and man's own instinctive cries (Farrar 1870). It is important to note that once the protohumans had the ability to mimic sounds and translate signals into meanings, then the ability to produce speech evolved, including onomatopoeia and the imitation of human emotional vocalizations.

Sign Language

Darwin, in a clear and detailed manner, described the role of gestures in the communication among humans. He was aware of the practice of sign language as a means of communication to deaf individuals (p. 58). He acknowledged the importance of gestures in conveying meaning, and he emphasized the fact that in order for people to be able to communicate between them they must see each other directly. Although he agreed that vocal communication can be aided by signs and gestures (p. 56), he criticized the gestural theorists. In his point of view, the vocal organs were significant to all mammals in the development of communication rather than the use of fingers. A major problem for gestural theories is to explain how such a system evolved from an initially iconic, holistic, meaningful system.

Sexual Selection in the Evolution of Language

Darwin's sexual selection theory states that sexually selected traits develop mostly in men who are considered to be more competitive and only at sexual maturity. Darwin, however, figured out that it is equally developed in males and females and is expressed very early in the biological development (Fitch 2005). There are few explanations to the difficulty that these facts pose. Firstly, during the musical protolanguage stage, sexual selection was the driving force, and song was

expressed mainly in males at sexual maturity. After the evolution of language, Fitch (2004) proposed that a selective force appeared to aid women to equally express language as men did and that language develops in earlier stages of life. The communication among the members of the family can be a selective force. Parent's communication with their offspring is an important aspect of their upbringing. Moreover, this can explain the reason language evolves at an early stage in the life of human beings. Language at an early stage of life can help children absorb their elder's knowledge and experience. Also, this kin selective force can explain the reason that language evolved only to humans and not to animals. People are going through life stages where they gain knowledge and experience, with very small reproductive output in relation to animals, which can reproduce from their early stage of life (Fitch 2007).

A different approach proposed by Miller (2001) is that sexual selection was an important driving force in human intellectual evolution, including speech. This hypothesis suggests that both sexes can choose and compete for high-quality partners. It is of paramount importance, however, to understand that this hypothesis does not explain the early development of language in infants. Finally, it is considered that sexual selection never played a role in the evolution of language (Miller 2001).

To summarize the compelling work of Darwin on the origins of language, it is important to note that Darwin proposed that the first step to language evolution was an increase in the mental capacities of humans. He agreed that both social and technological factors are significant in the selective roles. He used a wide comparative collection of data of nonhuman primate behavior and vertebrates, to propose his theories on the evolution of language. Darwin benefited from his studies on animals, and he used his observations to propose his theories on language development. Although he studied both the evolution of human and animals and described many traits shared between them, he concluded that language is unique only to humans.

Conclusion

The origin of human language despite its long history will probably remain uncertain. Nowadays, most scholars consider the early theories of how language emerged as invalid. These theories were the beginning for later researchers to develop their concepts on how language emerged, a topic that up until today it remains controversial. All these years, the evolution of language is one of the hardest topics under investigation, since there is not enough empirical evidence to adequately address the factor/s that initiated speech in our ancestors.

Definition

Eating disorders are a category of psychological disorders characterized by abnormal eating and related thoughts and emotions. People with eating disorders often have a preoccupation with food and their body image.

Introduction

Eating disorders (EDs) are a category of psychological disorders. The three main classifications in

the category of feeding and eating disorders are anorexia nervosa (AN), bulimia nervosa (BN), and binge eating disorder (BED). A fourth category is “eating disorders not otherwise specified,” in which individuals have eating-related problems but do not meet the diagnostic criteria for anorexia, bulimia, or binge eating. Eating disorders are characterized by abnormal eating behaviors and related thoughts and emotions (Parekh 2017). People who suffer from eating disorders are often preoccupied with food and their body image or weight and tend to be perfectionists who are extremely critical of themselves and their bodies (Parekh 2017). Eating disorders can be detrimental to one’s overall health and, in some cases, they can be life-threatening conditions. For example, anorexia is associated with increased risk of osteoporosis, anemia, and damage to the heart and brain (Brownell et al. 2011). Research has shown that individuals with anorexia have a mortality rate 18 times higher than peers who do not have eating disorders (Steinhausen 2009). Bulimia can result in mouth damage, gum disease, esophageal tears, and gastric ruptures (Parekh 2017). Furthermore, eating disorders are associated with an increased risk of suicide and increased rates of other psychological disorders such as depression and anxiety (Walden Behavioral Care 2019). Approximately 90% of those diagnosed with eating disorders are females (Hudson et al. 2007). However, the number of males diagnosed with eating disorders has been slowly increasing. When it comes to binge eating disorder, males and females are equally as likely to be affected (Brownell et al. 2011). Over recent decades, researchers have been studying the potential adaptive underpinnings of psychological characteristics which at nonclinical thresholds or in different ancestral environments may have conferred a survival or reproductive advantage, but which in their extreme form contribute to maladaptive eating behavior in contemporary humans. This chapter will describe the symptoms and diagnostic categories of eating disorders, discuss major hypotheses surrounding the evolution of the psychological and behavioral features of AN and BN, and highlight the role of food preferences and consumption behavior that evolved in ancestral environments that contributes to binge-eating disorder in a modern food environment.

Anorexia Nervosa and Bulimia Nervosa

Anorexia nervosa is an eating disorder specifically categorized by significantly low body weight, an intense fear of gaining weight or becoming fat, and disturbances in body image (Parekh 2017). The disorder can take one of two forms: restrictive subtype and binge-eating/purging subtype (National Institute of Mental Health 2018). The disorder typically emerges in adolescence, primarily between the ages of 15 and 19, and has the highest prevalence among females in Western societies (Brownell et al. 2011). However, eating disorders can affect people of all ages, racial/ethnic backgrounds, and genders (National Institute of Mental Health 2018). Bulimia nervosa, on the other hand, involves episodes of binge eating excessive quantities of food in a short amount of time and subsequent compensatory behavior to prevent weight gain by vomiting or using laxatives, enemas, or diuretics (Walden Behavioral Care 2019). This disorder can also be classified further into two types: purging and non-purging. Purging type is the most common form of bulimia and involves the abovementioned compensatory behaviors (Walden Behavioral Care 2019). The nonpurging type involves excessive exercise or fasting after a binge eating episode (Walden Behavioral Care 2019). Individuals with bulimia and anorexia share many features such as an extreme fear of fatness, a distorted body-image, a preoccupation with food and eating, and both primarily affect females of reproductive age in Western societies.

Since the mid-1970s, researchers have been interested in explaining the cause of eating disorders from a variety of perspectives. Some of the predominant theories are rooted in psychoanalytic approaches, sociocultural approaches, and biological approaches (see Salmon et al. 2009 for review). For example, one common sociocultural explanation attributes the cause of eating disorders to exposure to western ideals of female beauty and the internalization of a thin ideal (Salmon et al. 2009). Another set of studies from a biological approach have focused on the influence of genetics due to high heritability rates. Yet, despite the various theories that attempt to explain these disorders, they all face major limitations and

thus the causation of eating disorders still remains poorly understood (Faer et al. 2005; Salmon et al. 2009).

Recently, some researchers have approached the problem from a Darwinian perspective and developed evolutionary hypotheses in an attempt to better understand these disorders. Guisinger (2003) proposed the adapted to flee from famine hypothesis, which suggests that anorectic symptoms are manifestations of adaptive mechanisms to conditions of famine faced in our evolutionary past. These symptoms include restrictive food intake, denial of starvation, and hyperactivity, the latter of which has been evidenced by laboratory findings on rodents. Aside from this and some other minor theories, a few distinct evolutionary hypotheses can be identified in the current literature, all surrounding the ultimate causation of eating disorders. These include the Reproductive Suppression Model (Wasser and Barash 1983; Voland and Voland 1989), and theories that fall under the evolutionary concept of intrasexual competition, which includes the Sexual Competition Hypothesis (Abed 1998, 2012), and the theory that anorexia is a manipulative strategy imposed on subordinates by females (Mealey 2000).

The Reproductive Suppression Model (RSM)

We first consider the Reproductive Suppression Model (RSM) proposed by Wasser and Barash (1983). This theory rests on the assumption that not all conditions are equally favorable for investment in reproduction (Wasser and Barash 1983). For example, poor mental and physical health, social and psychological stressors accompanied by a perceived loss of social support, or the expectation that future conditions will be better than present conditions should trigger the suppression of reproduction. Individuals under this type of stress might be unsuited to pregnancy and raising offspring since these are cues of unfavorable environmental conditions (Wasser and Barash 1983). In these circumstances, the ability to delay reproduction is adaptive because it allows females to avoid reproduction when environmental conditions are not conducive to her offspring's survival,

and thus the benefits of suppressing reproduction often outweigh the costs. Females of many species including rabbits, elephant seals, and chimpanzees appear able to suppress or delay reproduction when environmental conditions are unfavorable. These mechanisms for “deciding” not to reproduce include suppression or delay of ovulation, delay of sexual maturation, and fetal miscarriage (Wasser and Barash 1983).

Other scholars have built on this initial theory and applied the RSM to humans to try to explain anorexia. They argue that it could be beneficial for human females to suppress reproductive potential when conditions are not favorable for investment in reproduction, and that body fat is minimized in situations when it would be disadvantageous for a girl to become pregnant (Surbey 1987; Voland and Voland 1989). By becoming anorexic, females can manipulate the timing of reproduction and stunt development. Research by Juda, Campbell, and Crawford (2004) supports the Reproductive Suppression Hypothesis, as they found women who perceived less support from their families have higher levels of dieting and decreased perceptions of parental readiness. They felt less prepared to raise a child and had more disordered eating attitudes and behaviors. Dieting is a mechanism that can be used to suppress reproduction; thus, these results lend support to the idea that dieting symptoms and perhaps eating disorders may be associated with an ancestral reproductive suppression mechanism (Juda et al. 2004).

This is highly relevant in modern day society which favors late maturation. Anorexia is a way to delay a female’s natural developmental trajectory by reducing fat through strict dietary behaviors. Most women require adipose tissue to make up approximately 22% of their body weight to maintain ovulation (Salmon et al. 2009). Women with anorexia approach a dangerously low weight to the point that their bodies often become incapable of supporting reproduction. Women with anorexia often experience cessation of their normal menstrual cycle (amenorrhea), since their body fat levels drop significantly below the average (Surbey 1987). Surbey (1987) concludes that it is unlikely that anorexia itself is the result of selection. Rather, what might have been selected

for is the ability of females to alter the timing of reproduction and anorexia nervosa appears to reflect this ability in response to environmental conditions (Surbey 1987). Voland and Voland (1989) noted that the patient’s age, initiating events, and the developmental context of AN seem to support the connection between reproductive suppression and AN. For example, 95% of AN cases had an onset under the age of 25, which corresponds with the ages at which women are most fecund (Voland and Voland 1989). The authors also incorporate kin selection theory to explain reproductive suppression in anorexic females. It has been proposed that the reproductive suppression that occurs in anorexic individuals may be adaptive since it allows for an increase of familial helping behavior at the cost of her reproductive suppression (Voland and Voland 1989). This could allow for an increase in her inclusive fitness, as noted in an analysis of female anorexic case histories by Voland and Voland (1989). Some studies have found that anorexic individuals are constantly and excessively worried about the welfare of their families and feel responsible for protecting their family members, and this worry, coupled with excessive helping behavior, was apparent in one of the case studies (Voland and Voland 1989).

Although the reproductive suppression model has received some support, it fails to address many key features of anorexia. For example, it cannot be used to explain why anorexia exists in postmenopausal women, why a less costly method to suppress reproduction would not have been selected for, and the distorted body image of those who have eating disorders. Furthermore, it fails to explain eating disorders in males and the mechanisms associated with other eating disorders.

Intrasexual Competition

Another evolutionary hypothesis surrounding eating disorders attempts to address some of these gaps and limitations faced by the previous explanations. The Sexual Competition Hypothesis (SCH) is based on Darwin’s (1859) theory of sexual selection, which has shaped systems

designed for mate attraction and retention. This theory explains that eating disorders, as well as the pursuit of thinness more generally, stem from the process of female intrasexual competition. Specifically, eating disorders are considered to be a state of “runaway” female intrasexual competition whereby the drive for thinness, which in moderation may be a useful and even adaptive strategy, instead spirals out of control in response to a range of genetic and/or environmental factors and becomes maladaptive (Abed 1998, 2012; Faer et al. 2005). Whereas men usually engage in more direct, physical forms of competition, women tend to engage in indirect forms of intrasexual competition. This often invokes the exclusion of rivals from the peer group, disparaging the competitor’s appearance and gossiping or spreading rumors about the rival’s fidelity or level of promiscuity (e.g., Davis et al. 2018). The goal of this form of intrasexual competition is to reduce the mate value and lower the desirability of a rival in the eyes of potential mates while simultaneously raising one’s own standing within the social network.

One other competitive mechanism women might employ within this domain, which bridges intersexual and intrasexual selection is the achievement and preservation of a nubile, sexually appealing body shape, as modeled by a low waist-to-hip ratio (WHR). Reproductive potential reaches its maximum 3–4 years after puberty, and this is also the time the nubile female body takes its full shape (Abed 1998). Men exhibit preferences for women of intermediate weight with a low WHR (Singh 1993). From this, it can be inferred that the extremely low body weight of those with anorexia is not an ideal imposed by men (Mealey 2000). Research demonstrates that the most attractive female WHR was judged to be 0.7–0.8 by both males and females (Singh 1994). Conversely, males with a low WHR were considered undesirable (Singh 1995). This gender specificity of the ideal WHR suggests that this trait is fundamental to mate attraction and could have evolved via sexual selection. A low WHR in women is viewed as an honest signal of a woman’s health and reproductive potential; it putatively indicates a higher estrogen ratio and

greater fecundity (Jasienska 2004). Thinness has also been shown to correlate with youthfulness (Singh 1993). Thus, the pursuit of thinness can be an adaptive strategy for mate attraction and retention, but only to a point. Once the female reaches a state of being clearly undernourished and emaciated, this is no longer attractive to males and is a threat to the woman’s health and wellbeing. The bodies of women with anorexia do not represent the attractive ideal, since their WHR is far from the 0.7 to 0.8 range. Furthermore, obvious malnutrition is a visual cue that can signal a woman’s inability to bear children. For example, having very low body fat can result in amenorrhea, the absence of ovulation and menstruation. The SCH is also able to explain pathological by-products such as reproductive suppression. The theory proposes that amenorrhea arises as a by-product of maladaptive runaway intrasexual competition (Abed 1998). Thus, for women with eating disorders, this drive for thinness becomes extreme and maladaptive.

There has generally been more empirical support for this hypothesis relative to the others reviewed thus far. For example, Faer et al. (2005) recently demonstrated that intrasexual competition for mates had positive direct relationship with body dissatisfaction and drive for thinness. Furthermore, it was a predictor of disordered eating behavior, suggesting that eating disorders are fundamentally linked to female intrasexual competitiveness (Faer et al. 2005). In an extension of this study by Abed et al. (2012), results demonstrated an association between female intrasexual competitiveness, status, and disordered eating behavior. This consistent finding lends more support to the SCH. In a study by Li, Smith, Griskevicius, Cason, and Bryan (2010), researchers found that for heterosexual women, but not homosexual women, intrasexual competition cues led to greater body image dissatisfaction and more restricted eating attitudes after exposure to competitive vs. noncompetitive cues of same-sex individuals. Specifically, this occurs after being exposed to a photo of a high-status competitor (Li et al. 2010). This study emphasizes the role that cues of high status competitors might be playing in the relationship between intrasexual competition and unhealthy eating behaviors.

More recently, Arnocky et al. (2016) showed that when women made social comparisons to attractive intrasexual rivals (measured either as an individual difference trait or by experimental priming task), females reported being more envious and in turn were more willing to use risky diet pills in order to lose weight.

One theory that strongly supports the SCH speculates that dominant women may attempt to inhibit the reproductive capacity of other women in order to diminish resource competition (Mealey 2000). In this case, anorexia is a tactic of reproductive suppression of subordinates by dominant females which manifests as an intense form of female intrasexual competition. It has been suggested that the reproductive manipulation of subordinate women by dominants is a type of competitive reproductive suppression (Wasser and Barash 1983). Mealey (2000) hypothesizes that anorexia could be a result of increases in female intrasexual competition, specifically through the media, whereby socially successful and dominant women manipulate young women who are potential competitors for good mates and other resources. From this perspective, anorexia is a consequence of social manipulation rather than a tactic for outcompeting rivals.

Another existing theory that lends support to the SCH is life history (LH) theory. Fast life history strategies are associated with greater risk-taking and short-term thinking, whereas slow life history strategies are associated with long-term thinking and careful consideration of risks (Abed et al. 2012). The SCH predicts that intense intrasexual competition for mates is associated with disordered eating behaviors, which has been supported by research (Abed et al. 2012). Further, recent research has shown that disordered eating behavior is predicted by a fast life history strategy (Abed et al. 2012). A fast life history strategy is associated with increased effort toward propagating one's genes in the short term and involves greater mating effort compared to a slower life history strategy. Thus, a fast life history strategy is consistent with the increased mating effort involved in high levels of female intrasexual competitiveness, and slow life history strategies are incompatible with increased levels of intrasexual competitiveness. Indeed, a slow life

history strategy was found negatively correlate with intrasexual competitiveness (Abed et al. 2012). Furthermore, it seems that a slow life history strategy incorporates increased behavioral regulation or self-control, which plays a protective role against female intrasexual competitiveness and the development of disordered eating behavior (Salmon et al. 2009). Thus, these results categorize eating disorders as pathologies of deficient behavioral regulation and indirectly associate disordered eating behaviors with faster life history strategies and high intrasexual competitiveness.

The SCH has recently been applied to a wider range of eating disorders, since the drive for thinness is apparent in both individuals with bulimia and anorexia. This hypothesis proposes that intense female intrasexual competitiveness is the ultimate cause of both eating disorders (Abed et al. 2012). However, this hypothesis does not come without its own limitations. Namely, it still makes it difficult to explain the existence of eating disorders in males; however, sex differences in response to intrasexual competition may explain why dietary restriction and AN is substantially more common in females. Additionally, this hypothesis rests upon the assumption that concern about physical attractiveness is universal. Since the Sexual Competition Hypothesis and the process of reproductive suppression both involve female intrasexual competition, it is also possible that both mechanisms might be working together in some cases (Abed 1998). This growing body of evidence suggests that the psychological and behavioral aspects that make up AN and BN have roots in evolutionary concepts such as intrasexual competitiveness and potentially the process of reproductive suppression in response to less than ideal environmental conditions, and that this lens can provide a more comprehensive understanding of the ultimate factors contributing to these disorders.

Binge Eating Disorder

Binge eating disorder is an eating disorder characterized by out-of-control episodes of binge eating in which individuals consume excessive

amounts of food in a short period of time (Striegel-Moore and Franko 2003). Individuals with BED eat until feeling uncomfortably full, eat much more rapidly than normal, eat large amounts of food even when they are not hungry, eat alone due to embarrassment, and experience marked distress regarding their behavior (Parekh 2017). The binge eating is not associated with the use of compensatory behaviors as in anorexia and bulimia. Compared to individuals with anorexia nervosa and bulimia nervosa who are usually underweight (AN) or normal to slightly overweight (BN), those with binge eating disorder are often overweight. Although binge eating disorder affects males and females at similar rates, men are significantly less likely to be diagnosed. This is because men are less likely than women to report distress over binge eating, which is a symptom required for diagnosis of BED (Striegel-Moore and Franko 2003).

Evolutionary theory can also help to inform the prevalence of this eating disorder. In our evolutionary history, foods high in fats and sugars were very hard to come by; therefore, it was advantageous to be able to store fat and sugar effectively and to develop psychophysiological mechanisms that motivate their consumption. It was also advantageous to overeat occasionally, since there were periods of food shortages that humans had to account for (King 2013). This was often due to seasonal variations in food, which resulted in both periods of food shortage and abundance, so it was adaptive to consume as much animal fat as possible when it was available (King 2013). Since then, the human diet has changed dramatically. Now, fats and sugars are widely available and easily accessible, which is contributing to widespread obesity and early loss of life (King 2013; Mealey 2000). Research has also found that it is not necessarily about physiological hunger signals that drive humans to seek out and consume large amounts of food; rather, it is the large variety of highly palatable foods (King 2013). Indeed, research shows that individuals with binge eating disorder consume more dessert and snack-food items than obese control subjects during meals, and highly palatable foods with a greater percentage of fat (Yanovski et al. 1993). Foods high in sugar and fat activate reward centers of the brain,

and thus we are driven to eat foods that are now widely available to us, yet can be very dangerous for our health in large quantities (King 2013). Binge eating disorder has been linked to severe obesity, diabetes, hypertension, and cardiovascular disease, and in general, a high body mass index can be detrimental to health and fertility (Parekh 2017). Today obesity constitutes a serious global epidemic in industrialized countries (Kardum et al. 2008).

Conclusion

Because the understanding of eating disorders constitutes a relatively new area of research, especially from an evolutionary perspective, it is important for evolutionary psychologists to continue to research the ultimate underpinnings of eating disorders and how these interact with more proximate causal and contributing factors to better inform clinical practice and treatment. For example, assessments may incorporate measures of intrasexual competitiveness. Further, a majority of the work to date has been conducted on individuals with anorexia nervosa, whereas the bodies of literature on bulimia, binge eating disorder, and other related eating disorders still require significantly more attention from an evolutionary psychological perspective.

Echolalia

Justin H. G. Williams
Institute of Medical Sciences, University of
Aberdeen, Aberdeen, UK

Synonyms

[Verbal mimicry](#)

Definition

The repetition of speech sounds, usually in a meaningless way

Introduction

The word *echolalia* is derived from the Greek words of echo (to repeat the sounds) and lalia (to speak). In Greek mythology, Echo was a talkative mountain nymph tasked with distracting Hera so that her husband Zeus could continue to enjoy his pleasures. Hera cursed her with the voice of the echo to speak only the last words of others.

Clinical Causes

In clinical practice, echolalia is recognized to be a symptom of a range of conditions, including

autism spectrum disorder, Tourette's syndrome, schizophrenia, and frontal brain damage caused by dementia or stroke. It is also a feature of typical early language development. It is a very common feature of autism, but a much less infrequent symptom of the other disorders. It is described in most detail in the manual of the Autism Diagnostic Observation Schedule (Lord et al. [2012](#)) where it is used as a diagnostic indicator.

Phenomenology

Echolalia may be delayed or immediate. As immediate echolalia, it usually consists of a repetition of the last words of someone else's speech. Echoing in this form can be a part of normal conversation if the listener is clarifying what has been said or is confirming that he or she has heard correctly. Immediate echolalia is characterized as being nonfunctional speech, being spoken without any purpose.

When echolalia is delayed, the repeated phrases occur sometime after they have been heard. They are more likely to be whole phrases and are often copied from television or other media sources, as well as from adults. The tone and inflection of the speech may be copied as well as speech content. Delayed echolalia may also be called "stereotyped speech." The phrases are often nonfunctional but not necessarily so. Sometimes they are incorporated into functional speech and may only be evident by seeming "odd," out of character, out of context, or being used in a repetitive way. For example, a child may use language which has a very adult-like or over formal quality. Sometimes children with autism spectrum disorder will adopt odd accents. For example, children in Scotland with autism may adopt an American accent through watching American television even though people around them are Scottish. There is no clear demarcation between normal patterns of repetitive speech and stereotyped speech or delayed echolalia, and many people have speech habits which include the use of repetitive elements that do not serve an effective function. For example, people might use a word or

phrase repetitively to preface the beginning of a sentence (e.g., “actually . . .,” “to be honest . . .”), or they might use certain words excessively (e.g., awesome, cool).

In autism, immediate echolalia tends to occur in association with little verbal ability and poorly developed language. Similarly, in brain damage such as stroke, it is likely to occur in association with other forms of aphasia where major speech centers have been damaged. In schizophrenia it is usually considered a feature of the catatonic subtype, which is relatively uncommon these days. In Tourette’s syndrome, schizophrenia, and autism, echolalia may be associated with *echopraxia*, involving the copying of limb movements and postures, or *mannerisms* and *tics* which are stereotyped patterns of movement which range from being very simple (tics) to complex (mannerisms). *Vocal tics* in association with echolalia are also repetitive patterns of vocal behavior but are not linguistic and may consist of grunts, coughs, or screams. Echolalia may also overlap with *coprolalia* in Tourette’s which is the compulsive expression of obscene language.

Evolutionary Aspects of Vocal Mimicry

In the animal world, humans were thought to be relatively unique along with songbirds, hummingbirds, and parrots in having the ability for vocal learning and speech mimicry (note that echolalia is often referred to as “parroting”). More recently, vocal learning is described in bats, cetaceans, elephants, and seals (Chakraborty and Jarvis 2015). Most animal species have a limited range of vocal expression which is largely innate (the chicken is a good example), and they are unable to mimic speech. A capacity for vocal learning in birds is evident by the presence of regional differences in vocalization which are independent of genetic differences. For example, in the United Kingdom, the chaffinch song differs across the country, showing evidence of dialect. In addition, chaffinches that are reared in isolation sing an impoverished song (Slater et al. 1984).

It is suggested that similarities between bird-song and human speech have emerged through

evolutionary convergence and that songbirds provide a model system for the study of speech acquisition in humans (Chakraborty and Jarvis 2015). This suggestion presupposes that immediate echolalia can be understood within a spectrum of social learning that ranges from “blind copying” or mimicry to intentional (goal-directed) imitation.

In the imitation literature, action copying more generally has been classified in this way, and a distinction has been made between imitation learning and mimicry (Whiten 2006). Mimicry involves perception of an action (whether visually or as a vocalization) which elicits execution of a previously learned motor program for the same action (or vocalization). In imitation, inference of the intention or motor plan associated with the action (including its purpose or “meaning”) occurs, and the action is reenacted in an intentional way to serve that same purpose. In birds, mimicry occurs but not imitation. The difference between typical functional speech and echolalia or stereotyped speech may therefore be best understood as whether it is directed and purposeful or whether it is nonfunctional. The caveat to this is that the phenomena of “over-imitation” is well recognized in typically developing young children, who will often copy a model’s behavior even though that behavior serves no useful purpose (Whiten et al. 2009). Therefore, as already mentioned, echolalia may be part of normal development.

Neurology of Echolalia

Speech control involves the coordination of about 40 muscles involved in respiratory, laryngeal, and articulatory control (Jürgens 2002). The motor neurons controlling this behavior are located in various brainstem nuclei providing output through the cranial nerves that include the vagus, glossopharyngeal, and hypoglossal. Like other aspects of voluntary motor control, control over the acoustic structure of vocalizations is carried out in a hierarchical manner, with behavior at a higher level encoded by the laryngeal motor cortex, and planning of speech encoded by Broca’s

area. Connections with sensory feedback mechanisms and mechanisms serving extrapyramidal control serve important regulatory functions. A second pathway involving anterior cingulate and periaqueductal gray matter (PAG) appears to serve the production of involuntary and innate motor behaviors such as the grunts or coughs that are characteristics of vocal tics in Tourette's syndrome (Jürgens 2009).

Echolalia would appear to reflect disinhibition of the neural pathways that serve to enact learned voluntary motor behaviors. The coexistence of echolalia with vocal tics suggests that anterior cingulate cortex (ACC) in medial prefrontal cortex may be important in regulating vocal mimicry as well as rates of innate utterances. Neuroimaging evidence indicates that the ACC mediates effects of social influences on action mimicry (Wang et al. 2011), as well as encoding the reward values of actions in humans (Lockwood et al. 2015). In animal studies bilateral lesions to anterior cingulate abolish the capacity to enact learned associations between vocal behaviors and rewards, providing further evidence that it regulates enactment of learned motor behaviors (Jürgens 2009). The supplementary motor area (SMA) is similarly implicated in both the control of imitation behavior (Koski et al. 2003) and amount of vocalization (Jürgens 2009), suggesting that it could also play a role. Echolalia in neurodevelopmental and neurodegenerative disorders suggests that it occurs when frontal lobe functions are damaged or undeveloped. Occurrence when Broca's area is damaged by stroke suggests it may occur when speech-planning mechanisms are damaged.

Conclusion

Echolalia is a word used to describe repetitive patterns of speech that mimic others. Echolalic speech can be delayed or immediate and fits within a spectrum of vocal and manual behaviors that range from features of typical social learning to pathological symptoms of neurological impairment.

Ecological Factors and Rape

Amanda DeSantis

Department of Clinical Psychology, University of Detroit Mercy, Detroit, MI, USA

Synonyms

Sexual abuse; Sexual aggression; Sexual coercion; Sexual violence

Definition

Rape may be defined as the use of force, or the threat to use force, to obtain sex. Ecological factors include any individual, social, biological, etc. factors that influence a living organism.

Introduction

Females are the choosier sex, in that they get to be choosier about with whom they copulate. This is due to females having bigger gametes than males, being born with a limited number of gametes, and having to carry the fertilized gamete (the zygote) until birth (Buss 2016). A female's reproductive success is contingent on her ability to choose to only conceive children that can be raised, to select the best father for her children, to persuade males to aid her and her children, to maximize the return on sexual favors she supplies, and to minimize the risk of violence or withdrawal of support by her partner and kin (Symons 1979). Rape circumvents female mate choice and thereby interferes with a central component of female reproductive strategy (Buss 2016). Determining the factors, both proximate and ultimate, surrounding rape may aid researchers in concluding how to extinguish this behavior.

Proximate Versus Ultimate Causes

Proximate causes of behavior are those that can be defined as the immediate causes of behavior. Proximate causes include factors such as environment, physiology, hormones, and genes. While proximate causes have to do with how developmental or physiological mechanisms cause something to happen, ultimate causes of behavior have to do with why particular proximate mechanism exist. According to Thornhill and Palmer (2000), "no aspect of life can be completely understood until both its proximate and its ultimate causation are fully known" (pp. 5). Regarding sexual coercion, rape appears to occur in all human societies, even modern ones, and is quite common during wartime. Its universality indicates that rape has likely arisen from ultimate causes, or adaptations, and that studying evolved differences between the sexes will aid in identifying the proximate causes (Thornhill and Palmer 2000).

The Thornhill Theory

Two leading theories exist in the evolutionary literature concerning why rape continues to be an existing human behavior. These theories, constructed by Randy Thornhill and Craig Palmer (2000), suggest either that rape evolved as a male sexual strategy or that rape is better understood as a by-product of male's sexual strategy of seeking out low-cost casual sex. Thornhill proposes that men have evolved a rape adaptation or specialized psychological mechanisms in which forced sex on unwilling women is a reproductive strategy that exists in all men's sexual repertoire (Buss 2016). Thornhill's theory proposes six specialized adaptations which include an assessment of vulnerability of the potential victim, a context-sensitive adaptation that motivates rape by men who lack sexual access to consenting partners, a preference for maximally fertile victims, an increase in sperm count in forced sex ejaculations compared with those occurring in consensual sex copulations, male sexual arousal and female

resistance, and context-specific marital rape when sperm competition might exist through infidelity. Support for Thornhill's hypothesis comes from research that suggests men are sexually aroused when exposed to sexual scenes, regardless of whether consent is involved (Buss 2016). However, evidence against this hypothesis comes from research that indicates that the presence of violence, evidence that the victim is in pain, and a disgust reaction from the victim all inhibit male sexual arousal (Malamuth 1986).

The Palmer Theory

Palmer proposes that rape is a by-product of other evolved male psychological mechanisms such as the desire for sexual variety and the capacity of men to use physical aggression to achieve a wide variety of goals (Buss 2016). Palmer draws from Symons' (1979) original rape as a by-product hypothesis which suggests that the primary adaptations responsible for rape include male's greater visual sexual arousal, greater autonomous sex drive, reduced ability to abstain from sexual activity, a greater desire for sexual variety, greater willingness to engage in impersonal sex, and less discrimination in sexual partner criteria. Palmer argues that many human behaviors are by-products of the intense sexual desires of human males and the sexual choosiness of human females. Some examples include child sexual abuse which can be seen as a way for males to gain access to individuals who are too young to control sexual access and masturbation which can be taken as a means of obtaining sexual gratification without meeting criteria for female's mate choice. To reject this hypothesis, a phenotypic feature of the human male analogous to rape-specific phenotypic features of other species, such as the notal organ in male scorpionflies, is needed (Thornhill and Palmer 2000). This feature would include some aspect of rape that cannot be accounted for by differences in male and female sexuality as described above. No such feature has yet to be identified. Thus far, no conclusion can be reached as to whether Thornhill or Palmer is correct.

Perpetrator Characteristics

Perpetrators of rape are almost invariably men, while most victims are women, though victims can also include children and men (Buss 2016). Other characteristics of perpetrators include hostility toward women, an endorsement of the idea that women secretly want to be raped, impulsiveness, low agreeableness, low empathy, hypermasculinity, and a high degree of sexual promiscuity (Malamuth et al. 1991). Age seems to play a role for the perpetrator as well. About half of all men arrested for rape between 1994 and 2010 were age 30 years and older, 34% were between the ages of 18% and 29%, and 15% were 17 years old or younger (Planty et al. 2013).

Mate value. In some instances, women are raped by "low mate value" men or men who are not willing to commit, have little to no resources, have low genetic quality, or are incapable of or unwilling to provide protection (Buss 2016). For these males, coercion may represent a desperate alternative (Thornhill and Palmer 2000). This concept is often referred to as the mate deprivation hypothesis (Lalumiere et al. 1996). If this forced copulation results in a pregnancy, the female is forced to bear and rear a child of someone who is not going to be helpful to her. Additionally, the child may be sickly or have genes that will make him or her unattractive to mates in the future. This is detrimental to the woman's reproductive fitness. In this scenario, the low mate value male reaps the benefits by forcing a mate ship that would not otherwise exist. Furthermore, if the woman is in a relationship with another man, or even if she is single, she risks being blamed or even punished for the rape. Her partner may then choose to leave, resulting in her having difficulty attaining a mate in the future (Buss 2016).

The mate deprivation hypothesis (Lalumiere et al. 1996) may be supported by the fact that much sexual coercion is committed by men in lower socioeconomic groups (Thornhill and Thornhill 1983). However, this finding may be misleading as men in lower socioeconomic groups commit all crimes at a higher rate (Thornhill and Palmer 2000). Additionally, lower rates of reporting may occur when the

rape is committed by men in higher social groups or because higher status men may be able to better evade arrest and conviction due to the ability to afford superior legal guidance (Buss 2016). Conversely, other research suggests that men who have a lot of sexual partners are more likely to use force (Lalumiere et al. 1996), and men who report higher future earning potential also report more physical coercion tactics in their mating relationships (Buss 2016).

Findings from a study done by Blake and Brooks (2018) propose that men who perceive themselves as disadvantaged in sexual competition (low mate value) are less likely to endorse acts of intimate partner violence (IPV) in conditions of gender equality, while this same condition evokes endorsement for IPV in high mate value men. Blake and Brooks hypothesized that the lack of endorsement is due to the low mate value men's fear that their reputation, which may be all that they have to offer a mate, will be destroyed if they are supportive of IPV and will lessen their chances of finding a mate. It is thought that when gender conditions are equal, men who are advantaged are at risk of their mates engaging in infidelity at work and have less control over their mates. Conversely, in conditions of gender inequality, high value men are less likely, and low mate value men are more likely to express attitudes accepting of IPV. When gender conditions are unequal, men with low mate value appear to capitalize on oppressive social norms and low female structural power, seeking to maintain dominance over their intimate partners through coercive violence, while high value men have little reason to support jealousy violence when conditions are in their favor.

Development. Development may also play a factor in why men commit acts of sexual violence. Men, who grow up with reduced parental investment and in environments in which social relationships tend to be short and uncommitted, tend to exhibit more sexually coercive tendencies in adulthood (Malamuth 1998). These men may have an expectation that sexual relationships should be brief and have a reduced ability to invest in women they are involved with. They also exhibit coercive sexual attitudes toward women and accept that aggression is a viable tactic for obtaining their goals, both sexual and

otherwise. Like the mate deprivation hypothesis, this developmental model suggests that men in disadvantaged groups may use violence as a last resort effort to attain mates.

Other Factors

Other factors that influence rates of rape include war time in which young attractive women are unprotected and punishment is unlikely (Thornhill and Palmer 2000), polygynous societies in which males are taught to be especially competitive, and societies with a high ratio of males which tend to experience more wars (Buss 2016). These contexts seem to suggest that male competition intensifies in times of a surplus of males.

Research supports the hypothesis that women who have protection from kin or male friends and mates are less likely to be raped (Buss 2016). High status men seem to have greater ability to prevent rape between their mates and other men (Thornhill and Palmer 2000). While women who are married may be subject to rape, married women, regardless of age, are less likely to be raped than same-age unmarried women (Buss 2016). Additionally, statistics on the occurrence of date rape, which may be between 15% and 20% of all college women, reveals that women not in long-term relationships are at considerable risk (Buss 2016).

Women who exclusively utilize short-term mating strategies are at a greater risk of both physical and sexual abuses (Buss 2016). Dating, it seems, is a common context for rape. A study containing over 10,000 victims of rape found that women between the ages of 16 and 35 were more likely to have been raped than any other age category (Thornhill and Thornhill 1983). Other research suggests that 85% of all rape victims are less than 60 years old (Buss 2016). Likely, the reason women of these ages are at a higher risk is due to being fertile. If rape is an adaptation or by-product, it seems reasonable that women who have the greatest chance of conceiving a child would be targeted most often. One startling statistic that evidences this theory is that pregnancy rates resulting from rape among reproductive-age women may be as high as 6.42% (Gottschall and Gottschall 2003). This

is highly shocking considering the consensual per-incident rate is only 3.1% (Gottschall and Gottschall 2003). This seems unlikely to be due to chance, especially with the advent of modern birth control.

If a woman is raped by her husband or long-term partner, it is likely a result of sexual jealousy and worry over real or imaged sexual infidelity (Buss 2016). Marital rape is also more likely during or immediately following a breakup. This finding may support the theory of rape as a sperm competition adaptation though there does not seem to be ample evidence yet to determine if there is a rape adaptation in human males (Symons 1979).

Conclusion

As David Buss (2016) concludes in his work *The Evolution of Desire*, it seems that a simple version of the mate deprivation hypothesis of rape is not likely to be correct. More likely is it that two context-specific rape adaptations have evolved: one that is contingent on when a male experiencing a mating failure and one in which the costs are so low that he can get away with it. Buss also notes that there are probably distinctive reasons for different scenarios (such as wartime versus date rape). Lumping these together will not help to determine the causes, proximate or ultimate.

Definition

How environmental/external conditions affect behavior.

Introduction

Local ecology has tremendous ultimate and proximal influence on human behavior through both evolutionary and developmental processes.

A number of theories predict a number of specific ecological influences for a variety of human behavior. Thus, a complete account of ecological influences is not possible. However, one theory in particular deserves special attention for the variety of diverse ecological conditions that it can bring together to explain a wide range of human behavior, life history theory. Here, life history theory is explained, the logic of life history theory is used to discuss specific environmental conditions and how they affect behavior, and evidence is presented that shows the theory-consistent impact of our local ecology on behavior. Finally, potential mediators of the effects of ecological conditions on human behavior are discussed.

Life History Theory

Life history theory has gone through substantial changes since its early focus on *r* versus *K* strategists and a focus on population density as a driving force in *r*-*K* selection (McArthur and Wilson 1967; Pianka 1970). Typical modern approaches using life history theory use a mix of evolutionary biology and behavioral ecology. At its core, life history theory is a theory about how organisms allocate their finite amount of bioenergetic and material resources (Figueredo et al. 2004; Stearns 1992). The two points on this continuum are somatic effort (the energy and resources allocated to the continual survival of an individual organism) and reproductive effort (the energy and resources for the production of new organisms). Reproductive effort can be further partitioned into mating effort (resources allocated to obtain and retain sexual partners), parental effort (resources allocated to enhance offspring survival), and nepotistic effort (resources allocated to enhance genetic relative's survival). These bioenergetic and material resource allocations represent trade-offs, as investment in one area (e.g., reproductive effort) means that the same effort cannot be allocated toward another area (e.g., somatic effort). To understand trade-offs in resource allocation, it is useful to contrast the strategies that result from these trade-offs.

Individuals who trade off reproductive over somatic effort and mating over parental/nepotistic effort exhibit a fast life history strategy. Individuals who trade off somatic over reproductive effort and parental/nepotistic over mating effort exhibit a slow life history strategy (Promislow and Harvey 1990; Figueredo et al. 2004, 2005, 2006). These life history differences are realized as a set of coordinated traits or behavioral responses that facilitate certain reproductive strategies and solve adaptive problems. These different strategies affect key variables such as the timing of reproductive events and the amount of investment in offspring. By coordinated, it is meant that traits should be consistent and reinforcing rather than inconsistent and interfering. For example, high sensation seeking and impulsivity are generally consistent and reinforcing traits, and life history theory would predict these traits to be related to a fast rather than slow life history strategy. Indeed, there has been research on individual differences in life history strategy from numerous disciplines including evolutionary biology, genetics, anthropology, and psychology. Psychological evidence, for example, indicates that fast life history strategists tend to have short-term mating, low parental investment, low group altruism, and higher criminality and are more prone to risky behaviors (Ellis 1988; Figueredo et al. 2004, 2005, 2006). Although life history theory predicts that traits like criminality and risky behavior will be related to a fast life history strategy, the theory does not predict that all fast life history strategists are criminals. Again, the coordinated traits should only generally be consistent with each other, and a fast life history strategy merely permits behavior like criminality.

Life History Theorized Environmental Contingencies

Although genetic influences are important (see Figueredo et al. 2004), specific changes in the local ecology are also theorized to affect the evolution and development of life history strategy. For brevity, these environmental contingencies were referred to by Reynolds and McCrea

(2015) collectively as life history contingencies. Ellis et al. (2009) extensively detail the variety of environmental conditions that compose these contingencies and grouped them into two main influences: harshness and unpredictability. Harshness is the rate of external factors that cause death and disability (i.e., extrinsic mortality). A variety of ecological conditions can fit under this umbrella, including pathogen stress, warfare, predation, and weather. The rate of death and disability, that is harshness, can also vary over time and space. In other words, it is not only the degree of harshness that is important, but how predictable or unpredictable it is. One reason life history theory is so useful when discussing ecological conditions is the ability of the theory to take seemingly separate ecological influences, like weather and warfare, and bring them together in a coherent manner.

Another reason the theory is useful is that it discusses a variety of ecological conditions and how they interact with each other to influence behavior. Additional ecological factors that interact to influence behavior include population density, intraspecific competition, and resource scarcity. Resource scarcity refers to the availability of nutritional and economic resources or lack thereof. Intraspecific competition is when members of the same species compete for limited resources; however, this can take multiple forms, one being a scramble competition and the other being contest competition (Ellis et al. 2009; Rogers 1992; Danchin and Cézilly 2008). In scramble competition, individuals have equal access to limited resources. As individuals consume resources, fewer resources are available to others. The competition is therefore indirect (Rogers 1992; Danchin and Cézilly 2008). In contest competition, individuals do not have equal access to resources. Some individuals suffer less or not at all in terms of growth and reproduction. This is due to evolved competitive adaptations for obtaining disproportionate amounts of resources. The distinction between these types of competition is important as it is contest competition that tends to characterize humans (Rogers 1992; Ellis et al. 2009).

All of these combined ecological conditions are theorized by LHT to lead to the development

and evolution of life history strategy. Certain combinations will lead to a slow life history strategy, whereas a different combination is predicted to lead to a fast life history strategy. Life history theory predicts that low harshness of the environment when combined with low population density, low resource scarcity, and low intraspecific competition should result in a fast life history strategy (Ellis et al. 2009). A reproductive over somatic effort trade-off is more advantageous in this case because the population is not near the carrying capacity. There are an abundance of resources available to the population. As a result, investing in somatic maintenance is not as valuable. Apportioning more energy and resources toward mating and reproduction effort, on the other hand, has valuable fitness effects.

However, low harshness of the environment combined with high population density, high resource scarcity, and high intraspecific competition should result in a slow life history strategy (Ellis et al. 2009). Here, resources allocated toward mating and reproductive effort is disadvantageous. These conditions require somatic maintenance, because the population is near its carrying capacity, meaning the environment, and hence the amount of resources available, can no longer sustain the number of individuals of that particular species in the population. In addition, intraspecific competition is high, which means conspecifics must engage in greater competition to gain access to resources including food, territories, and mates. According to life history theory, this should result in a more energetically sparring phenotype and the trade-off of somatic over reproductive effort. In these circumstances, selection would favor development of a slow life history strategy.

Life history strategy is also related to the link between the mortality rates among juveniles in the population. A high mortality rate among juveniles should result in a slow life history strategy. Under these conditions, parental effort can be translated into increases in offspring quality and resistance to environmental stressors. If the mortality rate is linked specifically with the adult proportion of the population, or the mortality rate is distributed throughout the population, a fast life history

strategy should develop. Here, parental effort cannot be translated into increases in resistance, because the environmental stressors are not juvenile specific. These examples demonstrate how using an LHT analysis results in the consideration of multiple environmental influences.

Unpredictability or the spatial-temporal variation of harshness in the environment results in similar predictions. For example, life history theory predicts that high environmental unpredictability and high variance in adult mortality-morbidity should lead to a fast life history strategy. To understand the reason for this prediction, it is useful to contrast this with a slow life history strategy trade-off. If an organism is making a somatic over reproductive effort trade-off in an environment characterized by unpredictability, they will be investing more heavily in themselves phenotypically. Thus, they will have offspring later, and if they have offspring, invest more heavily in them. However, due to the variation around the mean for adult life expectancy, the individual may perish before reproducing. Thus, a strategy with a reproductive over somatic effort trade-off will result in greater fitness. The organism's genes will be more likely to be passed down because they are more likely to reproduce before dying.

Empirical Evidence: Nonhumans

Research supports life history theory predictions in multiple species. Although the present work is focused on humans, research by Reznick and colleagues is briefly discussed as it is some of the most well-executed research and uses methods that would be untenable in the case of humans. For example, Reznick and colleagues conducted research on populations of guppies in low versus high predation areas. Results indicated that guppies in high predation areas display an FLHS and have traits like faster growth, earlier age at sexual maturation, and larger litter size (Reznick 1982; Reznick and Ghalambor 2005). As predicted by LHT, the high degree of nonage-specific environmental harshness is associated with phenotypic changes indicating a trade-off of

reproductive over somatic effort. As an extension of this research, guppies in high predation areas were moved to low predation areas. Eleven years and several generations later, the guppies had shifted to a slower life history strategy, displaying traits like later age at maturity and fewer offspring per litter (Reznick et al. 1996; Reznick and Shaw 1997).

The studies by Reznick and colleagues focus on nonhuman species and on the life history traits of body growth, age at sexual maturation, and litter size. Although many researchers agree on what the core life history traits are, such as timing of reproduction, there is less agreement regarding whether psychological traits should be considered life history traits. However, many psychological traits have been considered life history traits by some researchers, and some of these traits (e.g., criminal behavior and religiosity) can only be studied in humans (Ellis 1988; Figueredo et al. 2005). Research on humans also supports the hypothesized ecological effects on behavior.

Empirical Evidence: Humans

Research employing a variety of methodology has shown how ecological effects are associated with changes in a variety of important behavior. Longitudinal evidence comes from Brumbach et al. (2009) who investigated the role of harshness and unpredictability experienced early in life and how those conditions influence later life history strategy and deviant social behavior. Brumbach et al. (2009) used data from the National Longitudinal Study of Adolescent Health. Harshness was operationalized as self-reported exposure to violence from conspecifics and unpredictability as frequent changes or ongoing inconsistency. Using a structural equation modeling approach, the results showed that both environmental harshness and unpredictability during adolescence were associated with a number of important outcomes including health, sexual restrictiveness, and social deviance. Specifically, increased environmental unpredictability was associated with decreased health and increased social deviance. Increased environmental harshness was

associated with less sexually restrictive behavior and greater social deviance.

Similarly, Belsky et al. (2010) found a relationship between early maternal harshness, daughter's age of menarche, and risk taking. Using a subset of the families from the NICHD Study of Early Child Care and Youth Development, Belsky et al. (2010), using path analysis, found that greater maternal harshness at 54 months directly predicted social risk taking including using alcohol, drugs, and delinquency. Greater maternal harshness also directly predicted earlier age of menarche, which in turn predicted sexual risk taking.

Finally, also using a longitudinal design, Hampson et al. (2016) investigated the effects of harsh environments experienced in childhood and how these environments affect adjustment in emerging adulthood. Five cohorts of children (grades 1–5) from the Oregon Youth Substance Use Project were sampled and assessed through 1 year post-high school. Measurements of harshness included neighborhood quality and family poverty. Using structural equation modeling, results indicated that greater harshness experienced in early childhood directly predicted decreased parental investment in later childhood, and indirectly predicted favorable beliefs about substance use and willingness to use substances (such as alcohol and marijuana) at grade 9, and later use of substances and risky sexual behavior (grades 10–12).

Griskevicius et al. (2011) used both existing data and an experimental design to understand how environmental conditions influence reproductive timing. First, using data from the Uniform Crime Report, the US Census (2000), and the US Centers for Disease Control National Vital Statistics System (2004), Griskevicius et al. (2011) examined correlations between crime, socioeconomic status (SES), and reproductive timing. Results showed that violent crime was related to the age that people had children, even when controlling for SES. That is, in areas with higher violent crime rates, people tended to have children sooner. This pattern is consistent with LHT because adult mortality rates were related to having children sooner, an indication of a reproductive versus somatic effort trade-off. Griskevicius et al. (2011) further examined the relationship

between environmental contingencies and reproductive timing using experimental methodology. Harshness and unpredictability were manipulated via story primes. In the mortality prime condition, participants read a supposed news article about the increasing violence in the United States and how there are many random violent deaths (e.g., shootings in residential and commercial areas). The control condition was also formatted to look like a news article but it was about losing and finding a set of keys. Researchers also asked participants about their perceived resources (e.g., if they felt they were wealthy compared to others) as children and at present. Results showed a prime by perceived resource availability in childhood interaction. For people who grew up relatively poor, the mortality cues were associated with them wanting to reproduce sooner. A number of other experimental studies from multiple laboratories have shown a relationship between harshness and unpredictability with exploitative strategies and related variables such as short-term mating.

Exploitative strategies are one of the three fundamental strategies humans use to acquire reproductively relevant resources, and they consist of depriving other people of a resource while simultaneously enhancing one's own (Buss and Duntley 2008). In a within-subjects design with a sample of college students, Dunkel and Mathes (2011) used life expectancy manipulations to understand the effects on sexual coercion. The life expectancy manipulation involves having participants imagine different levels of mortality. Specifically, it consists of participants imagining that a doctor has just told them they have 5 months, 5 years, or 50 years left to live. Results indicated that the shorter life expectancy manipulation was related to an increased willingness to engage in sexual coercion. Also using the life expectancy manipulations, Dunkel et al. (2010) found that when participants imagined shorter life expectancies, they showed a greater interest in short-term mating. Finally, Dunkel et al. (2010) found shorter life expectancies were related to an increase in participants' inclination to express anger and be aggressive. Research by Reynolds and McCrea (2015, 2016a) extends this work.

Reynolds and McCrea (2015) used both a self-report measure called the Exploitative and Deceptive Resource Acquisition Strategy Scale (EDRASS) and a behavioral measure called the Dot Game to investigate the effects of a number of environmental contingencies. The EDRASS asks participants to imagine a scenario containing an exploitive behavior and rate how tempted they are to engage in the behavior. The Dot Game is a behavioral cheating game that can be played online and involves competing against another participant (fake participant) for money. Using some of the same primes from Griskevicius et al. (2011), in a between-subjects design, the results indicated that participants who read about the world being a dangerous uncertain place (i.e., harsh and unpredictable) engaged in greater exploitative behavior on the Dot Game. However, there were no effects of the prime that communicated that the world was high in population density, intraspecific competition, and resource scarcity. In a similar study, but using the EDRASS, Reynolds and McCrea (2015) could not replicate the effect of the harshness and unpredictability prime and continued to find non-significant effects of population density, intraspecific competition, and resource scarcity. To determine the reason for this discrepancy in findings, Reynolds and McCrea (2016a) conducted three studies in multiple populations. Results of the three studies found reliable effects of the harshness and unpredictability prime and the population density, intraspecific competition, and resource scarcity prime. However, contrary to predictions, participants who read about population density, intraspecific competition, and resource scarcity were more likely, compared to control, to be tempted to engage in exploitative behavior. Age was the most likely factor that caused the discrepancy in the previous findings, as Reynolds and McCrea (2016a) were able to replicate all effects with a younger college sample but not an older sample. This leads to an important question concerning the effects of ecology on behavior, is age one of the key moderators for ecological effects?

Evidence on this question is somewhat unclear. Simpson et al. (2012) found that unpredictability

experienced in early childhood (age 0–5) *but not* in later childhood (age 6–16) predicted sexual and risky behavior at age 23. Simpson et al. (2012) argued that the evidence suggested the first 5 years of life represented a developmentally sensitive period for environmental unpredictability. Griskevicius et al. (2011) also only found effects on timing of reproduction for the mortality prime, which communicated harshness and unpredictability, for people who grew up relatively poor. However, Hampson et al. (2016) found effects of harshness on children grades 1–5. Dunkel and colleagues and Reynolds and McCrea have found consistent main effects of specific environmental contingencies for college-aged people. As discussed above, Reynolds and McCrea (2016a) did find that less reliable effects are likely in older populations. Collectively, this evidence would seem to indicate that at least some behaviors are amenable to influence from some environmental contingencies at least until early adulthood, but other behaviors may show a different developmental sensitivity range. In other words, environmental contingencies can affect behavior, depending on the specific contingency, the specific behavior, and age.

Another important question for understanding ecological influences is what are the mediating psychological processes between environmental contingencies, like harshness, and behavioral strategies? According to life history theory, environmental influences like harshness, unpredictability, and resource scarcity should affect a suite of traits from intelligence and criminality to emotions and social skills. Traits should be generally mutually consistent with other traits, for example, high parental investment by a father should correspond with lower risk taking. However, while environmental influences are argued by multiple theories to affect a wide range of behavior, some traits may play a key role in mediating further change. Although there are many candidates, two potentially strong mediators include inhibitory self-control and time perspective.

Inhibitory self-control or inhibition regulation is the ability to inhibit responses motivated by short-term rewards in order to pursue more long-term benefits (Fujita 2011; Reynolds and McCrea

2016b). According to the dual component theory of inhibition regulation (DCTIR), self-control is an adaptation in the form of a computational module that monitors for certain impulsive mechanisms and inhibits them until the inhibition model has met its tolerance level or threshold. According to the DCTIR, specific environmental influences such as harshness and unpredictability interact with this mechanism in functional ways. Specifically, the DCTIR argues, consistent with life history theory, that high harshness and unpredictability lower threshold. As a result, it will be less likely a behavior will be inhibited for a long period of time, and the temptation of certain behaviors (such as risky behavior) may increase. In other words, one way that the environment may have such an impact on a wide range of behaviors is by not only directly changing certain traits like aggression or risk taking, but by changing regulatory mechanisms such as self-control. By affecting regulatory mechanisms, influence is exerted over all the systems to which the regulatory mechanism controls. There is some evidence already suggesting just such a role for self-control. There is extensive work demonstrating the relationship between self-control and criminal behavior, for example (Pratt and Cullen 2000). Most importantly, Dunkel et al. (2013) manipulated life expectancy and found that, under conditions of short life expectancy, there was a decrease in self-control and an increase in criminal intent. This relationship was further moderated by differences in life history strategy. Although there is much work to be done on the relationship between environmental influences and self-control, this may be a promising area of future research.

Another promising area of work involves the relationship of environmental contingencies with time perspective. As in self-control, time perspective is argued by some to be a mediating psychological process between environmental influences and behavior. Kruger et al. (2008) argued that individuals raised in unpredictable environments will have a more present oriented time perspective and thereby exhibit riskier behavioral strategies. To test this, Kruger et al. (2008) used items from the Monitoring the Future study from urban middle school students ($N = 607$). Positive and

negative aspects of social developmental environment, including physical safety, positive socialization neighborhood threats or harassment, witnessing fights, and being a victim of theft, were measured. Time perspective, including future and present orientation, was measured using items involving delay of gratification, planning for the future, importance of hard work, attitudes toward risky behavior, and the arbitrariness of goal-related outcomes. Behavioral strategies included measures of interpersonal aggression and illicit resource exploitation. Structural equation modeling results indicated that positive social developmental environment was associated with a future time perspective which then negatively predicted aggression. Negative social developmental environment was associated with a present oriented time perspective which then positively predicted aggression and resource exploitation. Thus, time perspective mediated the relationship between social developmental environment and phenotypic strategies.

Schechter and Francis (2010) found similar results in a population of Native American youth aged 10–19. Specifically, environmental risk and uncertainty were associated with internalizing these characteristics as mechanisms such as time perspective, which then predicted attitudes about risky behavior and investments in education. Although neither Schechter and Francis (2010) nor Kruger et al. (2008) discuss the computational structure of time perspective and how it is effected by environmental contingencies, as is the case with self-control (see Reynolds and McCrea 2016b), these studies clearly show an important mediating relationship that is only just being understood.

Conclusion

Ecological influences on human behavior can vary from harshness to population density. These contingencies have complex relationships that demand not only an understanding of how the contingencies interact with each other, but an understanding of the moderators (e.g., age) and mediators (e.g., self-control). The work by

Reznick and colleagues has demonstrated strong evidence of the influence of ecology on behavior. Research on humans is of course limited by ethical constraints in conducting similar experiments. However, research on humans is advantageous because psychological mediating processes are arguably easier to measure. Although there is considerable research on humans for environmental contingencies such as harshness and unpredictability, there is less on contingencies such as population density. Although there is much work to be done in this area, understanding ecological influences represents a critical piece to understand the mind and will continue to be a successful research area.

Ecological Influences on Parent–Offspring Conflict

Joshua J. Reynolds

University of Wyoming, Laramie, WY, USA

Synonyms

Conflict between parents and offspring; Environmental effects; Environmental contingencies

Definition

The environmental conditions that affect conflict between parent and child.

Introduction

To understand parent–offspring conflict and its ecological influences, Hamilton's rule is presented, which provides the basic logic for these conflicts. Life history theory is then briefly discussed, and the logic of these two approaches is used to understand how multiple ecological influences can affect parent–offspring conflict. Hamilton's rule defines the parameters by which altruistic behavior can evolve by natural selection. Thus, Hamilton's rule is a foundation for kin selection theory (Hamilton 1964a, b). Hamilton's rule states that altruistic behavior can evolve if $rB > C$, where C is the cost to the altruist, B is the benefit to the recipient, and r is the coefficient of relatedness. The coefficient of relatedness can range from 0 to 1 and represents the probability that, at any given locus, two individuals will share the same allele. Thus, for parent and offspring

$r = 0.5$, for siblings $r = 0.5$, and for half-siblings $r = 0.25$. A consequence of this relationship is that the higher the coefficient of relatedness, the more individuals can afford higher costs in order to benefit the other individual. In the case of parent–offspring relationships, parental investment involves resources that increase offspring chance survival, including time and food (Trivers 1972). For example, if a mother has two children and we assume equal costs and benefits, the mother should allocate her parental investment resources equally among the children. However, both the offspring and the mother are more related to themselves ($r = 1.0$) than with each other ($r = 0.5$). Additionally, not all offspring are equally good fitness vehicles. Some offspring will be more likely to survive and reproduce, and some offspring are more likely to benefit from certain types of parental care. This sets the stage for parent–offspring conflict because the offspring desires a disproportionate amount of parental investment resources (Schlomer et al. 2011). In other words, there are different levels of optimal parental investment from either the parent's or offspring's perspective, which leads to conflict. Parent–offspring conflict is thus viewed as general conflict of interest, rather than an observable instance of physical or verbal conflict. For example, there can be a conflict of interest in the mother–fetus relationship concerning fetal nutrition. According to parent–offspring conflict theory, conflicts of interest over the allocation of parental investment will be maintained by natural selection (Parker et al. 2002; Trivers 1974). There are a multitude of factors that can influence these conflicts, for example the age of the parents, the age of the child, the number of offspring, paternal certainty, step parenthood, and adoption. Here, the focus is on ecological influences, including environmental harshness, unpredictability, pathogen prevalence, resource scarcity, and dispersal.

Life History Theory

Life history theory focuses on the relationships between growth, reproduction, and survival

across the life cycle (Chisholm 1993). Life history theory predicts that there are trade-offs between investment in somatic effort (i.e., investment in development, growth, and body maintenance) and reproductive effort (i.e., investment in producing new organisms). Reproductive effort can be subdivided into mating effort (i.e., investment in obtaining and retaining mates) and parenting effort (i.e., investment in offspring). Trade-offs are fundamental because time and energy invested in one arena necessarily means that less can be invested in another. Ecological factors such as harshness determine which trade-offs are optimal for survival and reproduction.

Most trade-offs can be categorized as either a trade-off between current and future reproduction or a trade-off between offspring quantity and offspring quality (Chisholm 1999; Sterns 1992). For example, effort devoted to reproducing now means that the energy and resources cannot be used for future reproduction, the cost of which comes in the form of reduced number of future offspring, quality of future offspring, or survival of future offspring, as well as reduced parental growth and survival (Chisholm 1999). If the parent can be expected to engage in future breeding, the more resources are withheld from current reproduction. This naturally creates greater potential for conflict with existing offspring. Thus, different parental reproductive strategy trade-offs lead to different investments in offspring. These differences then lead to offspring solicitation for investment and create the potential for conflict (Schlomer et al. 2011). Therefore, conditions that affect parental reproductive strategy trade-offs can affect parent–offspring conflict.

Ecological Conditions

Harshness and Unpredictability

Ecological conditions that may affect parent–offspring conflict through parental reproductive strategy trade-offs include pathogen stress, warfare, predation, and weather cycles. What these ecological conditions have in common is that they are external causes of disability and death (i.e., extrinsic mortality). As an additional dimension,

these ecological conditions can vary over time and space. Life history theory summarizes these ecological conditions as harshness and unpredictability. Harshness is the rate of external factors causing disability and death. Unpredictability is the rate at which harshness varies over time and space (Ellis et al. 2009). Harshness and unpredictability can be relatively insensitive to the adaptive decisions of the organism. Although basic parental care benefits offspring, conditions of harshness and unpredictability create diminishing returns for parental investment (Pennington and Harpending 1988; Quinlan 2007). When there is high harshness and unpredictability, optimal levels of effort are lower because offspring are less likely to survive and reproduce. When harshness and unpredictability are low, parental investment can more successfully influence offspring survival and reproduction.

Although life history theory offers interesting predictions concerning ecological conditions and parent–offspring conflict, there has actually been little empirical work in this area. There is research on environmental conditions and aspects of life history that are related to parent–offspring conflict, such as the relationship between harshness and reproductive timing (e.g., Chisholm et al. 2005). However, much of this empirical work has focused on animal rather than human behavior. Nonetheless, existing human research supports the hypothesized relationships between ecological factors and parent–offspring conflict.

Belsky et al. (2012) investigated the relationships between both harshness and unpredictability experienced in families and parenting and early life history strategy. They examined 1,364 mothers and their offspring using longitudinal data from the NICHD Study of Early Child Care and Youth Development study. Belsky et al. (2012) measured a number of variables and modeled them using structural equation modeling. Of most significance to the present discussion was maternal sensitivity, defined as the ability of the mother to infer signals from the infant and respond appropriately to them (Ainsworth et al. 1974). Maternal sensitivity can be viewed as reflecting parental investment and thus has a

direct relationship to parent–offspring conflict (see Schlomer et al. 2011). Maternal sensitivity was measured through mother–child interactions during short videotaped sessions of semi-structured tasks. These data were collected when the children were between approximately 6 and 8 years old. Multiple coders then rated the interactions on supportive presence, respect for autonomy, and hostility. These scores were summed to create a general measure of maternal sensitivity. Results indicated that both harshness and unpredictability were uniquely related to maternal sensitivity.

Quinlan (2007) studied the relationship between extrinsic mortality factors, such as pathogen stress and warfare, with parental investment. One measure of parental effort was maternal care, which was measured as body contact with the infant, response to crying, and sleeping proximity. Results indicated that as the prevalence of warfare increased, maternal care decreased. Quinlan (2007) also measured weaning as a form of parental investment, which is particularly interesting from a parent–offspring conflict perspective. Following offspring birth, breastfeeding becomes the center of the mother–child relationship. There is good reason for this, as beyond basic nutritional needs which the mother provides to her offspring, breastfeeding contributes to the survival and overall health of the infant (e.g., health benefits include reduced risk of infections; Cunningham et al. 1991). Therefore, breastfeeding decisions such as duration and timing of weaning are important. This sets the stage for conflict because resources that the mother invests in breast feeding cannot be spent later on future reproduction. Thus, the optimal duration of breast feeding will differ from the parents' and the child's perspective, with longer durations advantageous from the perspective of the child and shorter durations advantageous from the perspective of the parents. Conflict due to the weaning dilemma should increase when maternal investment is allocated from breastfeeding toward producing new offspring. Multiple ecological and social conditions can influence weaning, and therefore potential conflict, such as social support, maternal workload, the availability of non-breast milk foods, and

socioeconomic status (McDade and Worthman 1998; Wander and Mattison 2013). In terms of harshness, the relationship with weaning can be complex. Quinlan (2007) found that higher pathogen levels were related to earlier weaning. In other words, when there is high pathogen load, which is a type of extrinsic mortality or harshness, offspring were weaned earlier. This is an expression of the current vs. future reproduction trade-off.

Using a longitudinal design and a structural equation modeling approach, Hampson et al. (2016) studied how harsh environments effect adjustment in emerging adulthood through parenting. Participants included five cohorts of children (grades 1–5) from the Oregon Youth Substance Use Project. Participants completed both interviews and questionnaires through 1 year post-high school. Hampson et al. (2016) measured harshness through neighborhood quality and family poverty. Parenting was assessed using three scales (monitoring, inconsistent discipline, and positive parenting) from the Alabama Parenting Questionnaire. Beliefs about substances (e.g., alcohol and marijuana) were assessed at grade 9, and risky sexual behavior and substance use were measured at grades 10–12. Adjustment 1 year post-high school was measured using life satisfaction, self-rated health, sociability, and depressive symptoms. Results indicated that harshness experienced in grades 1–6 directly predicted adjustment 1 year post-high school as well as parental investment at grade 8. In turn, parental investment at grade 8 predicted both beliefs about substances at grade 9 as well as risky sexual behaviors and substance use at grades 10–12. This evidence demonstrates that not only do harsh environments relate to parental investment, but that parental investment remains an important mediator for a number of life history relevant variables.

Resource Scarcity

In addition to ecological conditions that affect harshness and unpredictability, factors such as resource scarcity and dispersal may also affect parent–offspring conflict. Resource scarcity, that is, lack of nutritional and economic resources, can have a profound effect on parent–offspring conflict. One of the main effects is that resource

scarcity can limit how much can be invested in each child. As the number of offspring increases, investment in each offspring tends to decrease. Thus when resources are scarce, parents are forced to strategically allocate their investments. It is strategic because there is not equal division of investments among offspring; some offspring are favored. What determines being favored is partly due to the reproductive value of the offspring, i.e., their fitness. Offspring that have high fitness require less investment than do offspring with low fitness. Therefore, there should be greater conflict between low fitness offspring and parents. If the environment is rich in resources, then parents can afford to invest in needier offspring (Kushnick 2009). But when there is resource scarcity, this forces tough decisions. These decisions can even culminate in one of the more extreme examples of parent–offspring conflict, infanticide. Infanticide is common. For example, between 1995 and 2002 in England and Wales, infants had the highest homicide rate of any age group (Brookman and Nolan 2006). Fitness of the offspring may relate to infanticide. In cultures like the Ayoreo, when an infant is born, it is inspected for signs of deformity. If signs of deformity are evident, it is put in the hole and buried. In Brazilian shanty towns, which evidence significant resource scarcity, healthy infants are given preferential care, while less healthy infants are neglected (Scheper-Hughes 1992). In other words, parental investment is strategically allocated disproportionately to higher fitness infants. Again, there should be greater conflict between the offspring who are invested less in and the parents because the offspring are needier which increases demand for parental investment. Interestingly, historical events provide useful data on the relationship between resource scarcity and parent–offspring conflict.

The historical record is filled with incidences of famine. Famine, which is an extreme case of nutritional resource scarcity, has been linked with one of the earliest forms of parent–offspring conflict, that of between the mother and the fetus. The majority of fertilized eggs are not brought to full term. The majority of them are spontaneously aborted, with the most common cause likely

being genetic abnormalities (Simpson 2007). One of the most important environmental determinants of pregnancy outcomes is nutrition, and pregnancy is a time of increased nutritional needs, with fetal growth depending completely on the mother (King 2003). Historical cases of famine have been linked in many countries, across time, to an increase in intrauterine mortality. In Leningrad, 1942, citizens of the former Soviet Union endured one of the longest and costliest sieges in history via a military blockade by the German army. Increased levels of fetal wastage were observed during this period (Antonov 1947). On the German side, following food shortages after the war, there was a large increase in miscarriages reported in Frankfurt (Wynn and Wynn 1993). In the Netherlands, during the Dutch Hunger Winter (1944–1945), there was an increase in the number of stillbirths (Stein et al. 1975). In China, during 1959 to 1961, the Chinese people suffered through what has been called the Three Years of Great Chinese Famine, as well as the Great Leap Forward Famine. This was a period in China marked by drought, poor weather, and some unfortunate political policies that resulted in widespread famine. Using survey data that covered almost a quarter of a century, from a large number of pregnancy histories, Cai and Feng (2005) found an increase in miscarriages and stillbirth during the Great Leap Forward Famine. More recent studies continue to support the relationship between fetal wastage and famine.

In rural Varanasi, India, a longitudinal study of 49 villages from 1988 to 1992 found that low socioeconomic status and chronic undernutrition were associated with an increase in fetal wastage (Agarwal et al. 1998). Particularly interesting was that, whereas Agarwal et al. (1998) found that poor maternal nutrition was linked with an increase in still births, this was somewhat alleviated by a pregnancy interval of over 2 years. One way to interpret this is that the greater pregnancy interval period represented a life history trade-off of future over current reproduction. As a whole, the historical relationship between famine and fetal wastage supports the predicted life history theory relationship of resource scarcity and parent–offspring conflict.

Dispersal

Finally, ecological conditions such as spatial population structure may affect parent–offspring conflict. For example, dispersal involves the tendency of offspring to separate from locations where they originated (Mitteldorf and Wilson 2000). When there is limited dispersal, the spatial population structure is referred to as viscous. When the population is viscous, the correlation between average genetic relatedness and geographic proximity increases. There is not a large body of research currently on how dispersal affects parent–offspring conflict in humans. However, this may change with several new theoretical models predicting complex effects between the two. In terms of complexity, sometimes evolutionary conflicts are intensified as in parent–offspring conflict over sex allocation, whereas other times evolutionary conflicts are lessened, as in sexual conflict over mating rate (Rankin 2011; Kuijper and Johnstone 2012). In a recent extension of conventional models, Kuijper and Johnstone (2012) develop an evolutionary demographic model that involves the impact of limited dispersal on the intensity and resolution of parent–offspring conflict. According to Kuijper and Johnstone (2012), limited dispersal can increase local competition, including competition among related young. This competition can then reduce the cost of decline in maternal productivity. Kuijper and Johnstone (2012) argue that this favors greater offspring selfishness. In terms of resolving parent–offspring conflict, Kuijper and Johnstone (2012) argue that costly begging (a behavioral tactic for soliciting extra resources) is important, particularly the relationship between parental investment (supply) and begging (demand). The model developed by Kuijper and Johnstone (2012) predicts an interaction between these factors. When there is greater supply and less demand, parental investment should be higher in viscous populations, whereas when there is both great supply and demand, parental investment should be reduced in viscous populations. Considering that the advancement of technology has led to a greater potential for extremes in dispersal, such an approach has interesting implications for human behavior today.

Conclusion

This work discussed a range of ecological conditions, from pathogen stress to dispersal, and how they relate to parent–offspring conflict in humans. What should be evident is that there are a number of theoretical frameworks, such as parent–offspring conflict theory and life history theory, that make predictions about how ecological conditions affect parent–offspring conflict and resolution (see also Schlomer et al. 2011). Although some evidence for these predictions was discussed, it should be clear that there is a need for more empirical work directly investigating ecological conditions and parent–offspring conflict. Part of the problem stems from the difficulty of studying humans, who produce fewer offspring and have long lives. Nonetheless, with no shortage of good theory in this area, a major focus of empirical work should be on ecological conditions that influence parent–offspring conflict.

Habitat

Definition

The ecological niche corresponds to the sum total of unique ways in which a species is accommodated by and interacts with both biotic and abiotic factors in its surrounding ecology. Niches can be modeled as n -dimensional hypervolumes, whose dimensions correspond to the distribution of a species along abiotic and biotic gradients. Niches are idiosyncratic to species, with no two species sharing the same niche, although considerable overlap among niches can exist within a given ecosystem owing to competition.

Introduction

The term niche was first utilized in an ecological context by zoologist Joseph Grinnell (1917); however a rigorous quantitative definition of niche was not forthcoming until the 1950s. The concept has had a tumultuous history, having become unfashionable in ecology in the latter decades of the twentieth century owing to criticism from the philosophy of science and the rise of competing models. The concept has started to make a comeback in recent years however. This entry will first outline the early history of the concept before proceeding to discuss the quantitative ecological foundations of niche theory, as described by G. Evelyn Hutchinson. Criticisms leveled against niche theory will then be reviewed, and the recent

revival and expansion of the niche concept will be considered. Finally, in the conclusions, the applicability of niche theory to evolutionary psychology will be discussed.

Review

Early History

The term “niche” appears to have been first applied to ecology in 1917 by Joseph Grinnell. The Grinnellian niche essentially corresponds to the species’ *habitat*, or its physical location within an ecosystem. A subsequent attempt was made by the zoologist Charles Sutherland Elton (1927) to define the niche in relation to a species’ trophic interactions with other species, i.e., its associations with predators and prey. The Grinnellian niche can be considered analogous to a species’ *address* within an ecosystem, whereas the Eltonian niche can be considered analogous to a species’ *profession* or to its impacts on other species within an ecosystem. Both niche theories were descriptive or qualitative and made little impact on the development of ecology as a discipline.

The Hutchinsonian Niche

In the 1950s, limnologist G. Evelyn Hutchinson set out to answer the question “why are there so many kinds of animals?” (Hutchinson 1957, 1959). In doing so, he devised a novel quantitative model of the ecological niche that was based on the idea that a given species exhibits an idiosyncratic range of ecological requirements, which can be expressed in terms of the distribution of that species with respect to various environmental gradients. These gradients encompass factors, such as temperature, pH, salinity, pressure etc. Each gradient can be modeled as an axis in an n -dimensional graph, the species’ niche being the resultant hypervolume or centroid described by its distribution throughout this n -dimensional space. Thus Hutchinson’s solution to his question was that because environments contain many different gradients, they can sustain many different species – with no two species being described by precisely the same hypervolume or centroid. This

model allows for competition and coexistence among species to be more precisely described also. In considering this, Hutchinson partitioned the species niche into *fundamental* and *realized* niche space, with the former corresponding to the entirety of environmental gradients that are suitable for a given species and the latter corresponding to the portion of the niche actually realized by a particular species and that is unshared with other species. In practice a species never realizes its fundamental niche as *competition* between species for resources prevents this from occurring. A species’ realized niche therefore results from *character displacements* and *trade-offs* that facilitate *coexistence*. To illustrate this, Hutchinson emphasized the role played by limits imposed on the degree of morphological similarity between closely related species sharing the same habitat, such as size, which keeps the two species from *competitively excluding* one another. Hutchinson proposed a theory of *limiting similarity*, which could be expressed as a ratio of morphological similarity between species corresponding to 1.3:1 (i.e., two closely related species can coexist if one is 1.3 times the size of the other). This came to be known as *Hutchinson’s ratio*.

Criticisms

In the 1970s, niche theory came under considerable criticism, which eventually led to the concept falling out of favor in ecology. The initial criticisms were philosophical in nature. The Popperian school of scientific philosophy emphasizes the significance of being able to falsify scientific hypotheses to the process of sorting among competing theories. Niche theory, it was claimed, had not been tested in such a way that could theoretically lead to its falsification. It was also noted that biogeographical models, which deal with ecological processes at large spatial and temporal scales, could predict species diversity and abundances using only *metapopulation dynamics* (i.e., the assumption of equal rates of immigration, emigration, births, deaths, etc.), without assuming the existence of species-specific niches (Simberloff 1978; Strong et al. 1979). In applying these biogeographical modeling

assumptions to smaller spatial scales – the traditional domain of niche theory – the ecologist Stephen Hubbell (2001) developed the *neutral theory of biogeography and biodiversity*, which can be considered an effective null hypothesis to niche theory as species abundances and diversities within a given community are predicted based on the explicit assumption of strict ecological equivalence among species.

Revival and Expansion

Hubbell's neutral theory has not been received uncritically by ecologists, and while it has enjoyed some measure of empirical success in predicting species abundances in ecosystems at equilibrium, in non-equilibrium ecosystems, it has had far more limited success (Chase and Leibold 2003). Alternative *idiosyncratic models*, making the assumption of absolute species ecological uniqueness (an extreme form of the niche assumption), have also been found to predict species abundances at least as well as neutral models (Pueyo et al. 2007), indicating the existence of a large family of predictive models, among which model selection might profitably be based on the degree to which they make realistic assumptions. Ecologists Jonathan M. Chase and Mathew A. Leibold (2003) have pushed for a revival of the niche concept, arguing that further evolutions of the definition of ecological niche should take into consideration both the requirements of species – this being central to the Grinnellian and Hutchinsonian niche concepts and their impacts on other species – this being central to the Eltonian “feeding” niche concept. The concept of the *evolutionary niche* has also been proposed. Unlike the ecological niche, which is essentially a snapshot of competition pressures operating on a given species at a particular point in time, the evolutionary niche takes as its dimensions the sum of selection pressures operating a species, which have shaped the species' present ecological requirements and impacts (Chase and Leibold 2003). A closely related concept is *niche construction* which is based on the idea that species are not passive with respect to their environments but ineptively modify or construct their niches so as to suit their idiosyncratic needs, and in so doing the

constructed niche becomes part of the species' *ecological inheritance system*. This can be seen in the case of pocket gophers (Geomyidae family) whose social and reproductive ecology involves the creation of elaborate networks of tunnels, which can be “transmitted” across multiple generations (Odling-Smee et al. 2003). In this model, changes in the way in which a species constructs its niche can alter its ecological inheritance in such a way that feeds back onto the species' gene frequencies (i.e., exploitation of a new resource bringing two species into competition); thus a species' evolutionary niche coevolves with and ultimately drives the evolutionary trajectory of that species.

Conclusion

The niche concept, and in particular the concept of the evolutionary niche and niche construction, has significant implications for evolutionary psychology. In many respects that concept of the *Environment of Evolutionary Adaptedness* from “classical” evolutionary psychology (Tooby and Cosmides 1990) has the characteristics of an evolutionary niche, with the sum of the places and times of adaptive relevance in the Pleistocene constituting its dimensions and the various cognitive modules being adaptations to its contours. *Evolutionary mismatch* occurs when a feature of the human mind adapted to a particular dimension of the evolutionary niche interacts with an evolutionary novel feature of the contemporary built environment in such a way that yields an evolutionarily suboptimal behavioral manifestation. This has been challenged however by proponents of niche construction (Odling-Smee et al. 2003), who argue that *Homo sapiens* is an aggressively niche-constructing species by virtue of its high intelligence and that far from being removed from evolutionary relevant environments, niche construction has played and continues to play a critical role in the evolution of the species, such as in the case of *culture-gene coevolution*, where gene frequency change-initiated alterations to the contours of the *cultural niche* create novel selection pressures, which feed back onto

the cultural niche via their impacts on gene frequencies, leading to runaway selection (as in the case of the spread of lactase persistence). Better understanding of the dynamics of mutual transaction between biological and ecological inheritance in niche-constructing taxa might therefore pave the way for a post-neo-Darwinian evolutionary ecology (Odling-Smee et al. 2003).

Ecology: The relationships between living organisms (including humans) and their environment.

Introduction

Most research on sociosexuality has focused on the individual level of analysis, investigating either between-person differences or differences between men and women (e.g., Simpson and Gangestad 1991). Other work suggests that sociosexuality also varies extensively across cultures around the globe (e.g., Schmitt 2005) and that this variation – far from being stochastic – is at least

partly due to predictable variation in different ecological demands.

Cultural Variation in Sociosexuality

In the largest systematic investigation into sociosexuality around the world to date, Schmitt (2005, as part of the International Sexuality Description Project) administered the Sociosexual Orientation Inventory (Simpson and Gangestad 1991) in 26 languages and 48 countries to over 14,000 people around the globe. This investigation revealed extensive cross-country variation in sociosexuality scores across countries: On average, Bolivians reported being more sociosexually unrestricted than Belgians and Slovenians more unrestricted than South Koreans. These differences attest to the substantial plasticity in human sociosexuality. Despite this large variation across countries a notable consistency also emerged: Consonant with parental investment theory (Trivers 1972), men in each of the 48 countries reported a significantly less restricted sociosexuality than women. Although the magnitude of the sex differences varied across countries they were generally large, with an average effect size of $d = 0.74$ across the entire sample.

Schmitt was also able to test potential causes of this cross-country variation. One demographic variable that emerged as a strong predictor was sex ratio. Sex ratio theory predicts that relatively more men than women in a country would be associated with more restricted sociosexuality, given that increased competition for women allows them to have greater influence than men over sociosexual norms. Indeed, Schmitt found that higher ratios of men were associated with more restricted sociosexuality in a country. Second, Schmitt tested the impact of ecological demands on sociosexuality. Consistent with Strategic Pluralism Theory, which stresses the higher adaptive value of biparental care and restricted sociosexuality in harsher ecologies (Gangestad and Simpson 2000), analyses revealed that people were more sociosexually restricted in countries characterized by more demanding ecologies (characterized by factors such as higher infant mortality and child malnutrition).

Finally, Schmitt tested potential causes of the variability of magnitude of sex differences between countries. Again consistent with Strategic Pluralism Theory, which predicts that women's sexuality should be more facultatively calibrated to demands within the local ecology, results revealed that women's sociosexuality was much more influenced by ecological demands than was men's. Results also revealed the influence of a social variable: Increased levels of gender equity (assessed by variables such as percentage of women in politics and divorce rates) were associated with much smaller sex differences in sociosexual orientation within a country.

Disease Threat and Variation in Sociosexuality

Infectious disease has posed one of the largest threats to human welfare and survival throughout human history, likely accounting for more deaths than any other factor (Inhorn and Brown 1990; Wolfe et al. 2007). The magnitude of this threat, however, varies between regions and ecologies. Along with evolved physiological adaptations to mitigate this threat (such as the immune system), humans have also developed culture-specific behavioral norms and practices that serve as defenses against infectious disease which are often evoked by the local ecology.

Sexual behavior provides much opportunity for disease transmission, and more sexually promiscuous behavior is associated with an increased risk of contracting diseases and spreading these diseases to others. However, a more unrestricted sociosexual orientation can also have specific kinds of adaptive benefits – providing, for example, the opportunity to produce more offspring (see Gangestad Sociosexuality). These benefits must be weighed against the disease-related costs, and this cost/benefit ratio varies depending upon the prevalence of disease-causing pathogens. Where pathogen prevalence is higher, the costs of unrestricted sexuality are more likely to outweigh the benefits, whereas in places characterized by lower pathogen prevalence the benefits

are more likely to outweigh the costs. This logic leads to the hypothesis that greater pathogen prevalence predicts more restricted sociosexuality.

Cross-national evidence provides support for this hypothesis (Schaller and Murray 2008). In places with a higher level of historical pathogen prevalence, both men and women report being more sexually restricted (r 's for men and women were -0.27 and -0.62 , respectively). This effect is stronger for female scores, and this sex difference in effect sizes fits with the cost/benefit framework and with Strategic Pluralism Theory more generally (Gangestad and Simpson 2000). Men have a lower minimum level of parental investment than do women (see Gangestad Sociosexuality); thus, the fitness benefits associated with unrestricted sexual behavior are likely to be greater among men than among women. Therefore, for men only, these benefits may outweigh the costs (disease transmission) even at relatively high levels of pathogen prevalence. Among women, however, the benefits of unrestricted sexuality are relatively minimal and so are more likely to be outweighed by disease-related costs as pathogen prevalence increases. Consistent with the conceptual framework, additional results revealed that cross-national variation in women's unrestricted sexual attitudes were predicted especially strongly by the prevalence of human-transmitted non-zoonotic diseases, compared to the prevalence of zoonotic diseases (Thornhill et al. 2010). All of these relationships were robust when controlling for other potential causes of variation in sociosexuality, such as economic development and inequality, and other ecological demands.

Recent additional results from analyses of Pew survey data from 40 countries (www.pewglobal.org/2014/04/15/global-morality) also speak to the influence of disease threat for cultural variation in sociosexuality. This survey found that the acceptance of nonmarital sex differs widely across cultures: Whereas 97 % of Indonesians say that premarital sex is wrong, for example, only 11 % of Italians do. Murray and Schaller (2016) tested whether acceptance of premarital sex was associated with disease threat. Indeed, they found that historical pathogen prevalence strongly predicts the percentage of people within a country who

state that premarital sex is morally wrong ($r = 0.65, p < 0.001$). Consistent with the causal interpretation, acceptance of premarital sex was more strongly predicted by historical rather than contemporary pathogen prevalence.

Other work at the psychological level also indirectly supports the influence of disease threat for sociosexuality. First, chronic *perceived* risk of disease transmission is negatively associated with promiscuous sociosexuality (Murray et al. 2013). Of more inferential utility is the finding that people high in worry about disease became *more* sociosexually restricted when the threat of disease (but not a disease-irrelevant threat) was made salient (Murray et al. 2013). Additional analyses suggested that these effects were especially strong for women. These results also provide further evidence for adaptively flexible mechanisms which respond to immediate ecological circumstances.

Conclusion

Taken together, this work highlights the importance of ecological factors in the calibration of sociosexuality. The existing evidence clearly shows that neither gender is rigidly predisposed to a single mating strategy. However, these data also suggest that, at present, no ecological or social pressure is strong enough to make women on average more sociosexually unrestricted than men.

Environmental factors associated with marital harmony

Definition

The study of physical and social environmental factors influencing pair-bond stability and dissolution.

Introduction

Humans are a pair-bonding species, and this is reflected in our behavior and physiology (Quinlan 2008). While their form and duration varies, pair-bonds exist in all human societies—and there are very few, if any, exceptions to this rule. To understand the stability of pair-bonds, it is useful to look at the contexts under which they are unstable, to examine the factors that increase the probability of divorce or dissolution. These factors have been well studied by scholars in sociology, psychology, anthropology, medicine, and law. Despite this, the *ecological* factors driving pair-bond stability and divorce have received much less attention in humans as they have in studies of other pair-bonding organisms, such as birds.

This entry will provide a selective and brief account of (1) the behavioral ecological approach to pair-bond stability in humans; (2) mate desertion theory, the primary theoretical approach used in studies of human pair-bonding, and empirical tests of the idea; and (3) studies that have gone beyond the limitations of mate desertion theory.

Behavioral Ecology and Pair-Bond Stability

Human behavioral ecology is the study of human behavior in evolutionary and ecological context. Under the assumptions of this framework, humans are viewed as actors whose behavior is shaped by genetic and cultural evolutionary mechanisms to maximize inclusive fitness given the constraints of prevailing ecological conditions. Adopting the wording of Winterhalder and Smith (2000), a typical HBE hypothesis might take the following form:

- In context X, stay in a pair-bond because it maximizes inclusive fitness.
- In context Y, leave an existing pair-bond because it maximizes inclusive fitness.

These hypotheses are often derived from mathematically or graphically formulated optimality models. When the payoffs are frequency dependent (i.e., one actor's payoff depends on what the other actors are doing), as is often the case with pair-bonding, game theory provides the best-fitting analytical tools. The idea of an evolutionarily stable strategy (ESS) comes from this body of theory and can be defined as "a strategy such that if all members of a population adopt it, then no mutant strategy could invade the population under the influence of natural selection" (Maynard Smith 1982, p. 10).

Pair-bonds can dissolve via divorce, abandonment, or death. The first two causes of dissolution should occur when one or both in the pair can increase their fitness by doing so, for instance, by having a reasonable probability of finding a better mate. The third cause, mortality, is out of the actors' control (except, perhaps, in the case of spousal homicide). Despite these fundamental differences, both should be influenced by ecological conditions.

Mate Desertion Theory

Maynard Smith (1977, 1982) can be credited for bringing game theory to bear on the problem of mate desertion. In his models, the decision to stay or desert depends on the *frequency-dependent* fitness payoffs for staying (parenting effort) as traded off against a *fixed* payoff for seeking additional mating opportunity (mating effort). While the prospective nature of the models improves on existing ones that viewed past investments as reasonable drivers of future ones, they are now viewed as having a serious shortcoming (Houston et al. 2013). The mating benefits of desertion should be a frequency-dependent, rather than fixed, function of how many opposite-sex individuals have left their own pairing in favor of the mating pool. More recent models of mate desertion account for this.

The major conclusions drawn from these models are as follows. First, mate desertion will occur when the fitness benefits of seeking additional mates outweighs the decrease in offspring survival caused by reducing the number of individuals providing parental care. Second, desertion by none, both, or one partner can be an evolutionary stable strategy. This is illustrated graphically in Fig. 1 using examples from Lazarus (1990). In these illustrations, the fitness accrued between the start (t_0) and end (t_e) of the period of parental care for biparental care is V_2 , uniparental care is V_1 , and no care is V_0 . The fitness accrued in searching for another mate is M_1 for the partner with the higher marginal gains and M_2 for the partner with the lower marginal gains. In (a), neither partner deserts because $V_1 + M_1 < V_2$ and $V_1 + M_2 < V_2$. In both (b) and (c), the first partner deserts at t_1 because $V_1 + M_1 > V_2$. In (b) the second partner does not desert because $V_0 + M_2 < V_1$. In (c) the second partner deserts the offspring at t_2 because $V_0 + M_2 > V_1$.

Harpending and Draper (1986) argued for the application of mate desertion theory to the problem of human pair-bond stability, identifying specific aspects of the socioeconomic environment that shape the payoffs. They pointed to fertility rates as a measure of the potential payoffs for mating and care-dependent child mortality rates as a measure of the potential payoffs for fathering. In relatively good environments, where increases in paternal care lead to increases in offspring survivorship, more stable pair-bonds are expected compared to relatively bad environments where paternal care is unlikely to increase offspring survivorship. The focus on payoffs to males was due in large part to males being the ones with higher marginal payoffs to mating (M_1 in Fig. 1) and, thus, the more likely to desert for these reasons.

Hurtado and Hill (1992) tested hypotheses derived from mate desertion theory using data from two South American foraging societies, the Ache and Hiwi. Blurton Jones et al. (2000) extended the analyses to include two African foraging societies, the !Kung and Hadza. They argued that societies with higher pair-bond stability should have (a) higher payoffs for fathering effort, measured as differences between

Ecology of Pair-Bond Stability, Fig. 1 Illustrations adapted from Lazarus' (1990) model of mate desertion, depicting scenarios where (a) neither partner deserts, (b) one partner deserts, and (c) both partners desert. The following parameters describe fitness payoffs: V_2 is the payoff for biparental care, V_1 for uniparental care, V_0 for no care;

M_1 is the payoff to looking for an additional mate for partner 1, and M_2 is the payoff to looking for an additional mate for partner 2. The labels on the time axis describe the following: t_0 is the start and t_e is the end of the period of parental care, t_1 is the timing of desertion for partner 1, and t_2 is the timing of desertion for partner 2

father-present and father-absent child mortality rates (i.e., the “fathering effect”); (b) lower pay-offs for mating effort, as measured by fertility rates (i.e., fertility units per male or FU/male); and (c) a higher value for the trade-off between the two, as measured by the parenting/mating index. As shown in Fig. 2, they found that the payoff for mating was a better predictor of pair-bond stability than the payoff for fathering. The trade-off measure was also supported, albeit not as the predicted gradient. Blurton Jones et al. (2000)

argued that their results cast doubt at previous accounts of the primacy of provisioning for the evolution of human pair-bonding (Quinlan 2008).

While paternal care may have an important function in supporting lactation (Marlowe 2003; Quinlan and Quinlan 2007, 2008), it does not covary as predictably with environmental uncertainty as does maternal care (Quinlan 2007). In Sear and Mace's (2008) review of studies of the effect of fathers on offspring survival, they found markedly mixed results with less than half

Ecology of Pair-Bond Stability, Fig. 2 Fathering effect, FU/male, and their trade-off in four societies ordered by pair-bond stability, the inverse of divorce rates. Only the measure of payoff for mating effort, and less so the trade-

off measure, approximates the predicted gradient by pair-bond stability (Created using data from Table 4.4 in Blurton Jones et al. (2000, p. 78))

showing a clear positive fathering effect. Studies of longer-term effects of fathers on offspring success appear mixed as well (e.g., Winking et al. 2011). This may be, in part, because children are cared for by a variety of kin, and this may buffer children against father absence. Indeed, Quinlan and Quinlan (2007) showed that availability of helpers led to higher incidence of divorce in a study of 58 small-scale societies. Taken together, the evidence supports Blurton Jones et al. (2000) contention that mating may outweigh fathering in the evolution of human pair-bonding.

One of the most important aspects of the socio-ecological environment shaping the payoff to mating effort is the operational sex ratio (OSR) — a measure of the number of males to females currently available for mating. With a male-biased OSR, competition for mating opportunities is much more intense, and thus, males do better to stay in existing pair-bonds; with a female-biased OSR, on the other hand, males may increase their fitness by deserting their mate in favor of the increased possibility of acquiring a mate of better quality (Blurton Jones et al. 2000; Ellsworth et al. 2015). These hypotheses were overwhelmingly supported in a recent comparative study of pair-bonding birds (Liker et al. 2014), and there is accumulating evidence

along the same lines in humans (e.g., Barber 2003; Kruger 2009).

Other Costs and Benefits in Ecological Context

The major shortcoming of mate desertion theory is that the actual benefits of pair-bond stability go beyond the immediate parental care ramifications, and the actual costs go beyond the current breeding attempt. Pair-bond dissolution should be favored any time one or both in the pair can increase their fitness by seeking another mate. As Choudhury (1995) puts it, pair-bond dissolution should be “viewed as a reproductive strategy by an individual to maximize its own fitness” and to ascertain an individual’s “net benefit from divorce one must compare the expected future gain in fitness with the new mate versus the expected gain with the old mate” (p. 414). Winking and Gurven (2011) measured these quantities with data from Tsimane hunter/horticulturalists from Bolivia and concluded that males can increase their fitness via divorce.

Once one moves beyond mate desertion theory, however, little work has been done in developing quantitatively precise models of divorce that account for ecology. McNamara (1999), for

example, built an ESS model of divorce, but it focused on intrinsic qualities of the partners rather than extrinsic qualities of the environment. The model predicted that high-quality individuals should be more likely to seek greener pastures than low-quality individuals and that the most stable pair-bonds will be between individuals of similar quality. This suggests that sexual conflict theory may be necessary to understand divorce, as the fitness increase enjoyed by the initiator is a fitness decrease for the abandoned. This appears to be true in at least some cases in humans. Käär et al. (1998), for instance, showed that divorce led to increased reproductive success in males but not females in the eighteenth- to twentieth-century Sami populations from Finland.

Marital satisfaction appears to hinge on ecologically variable factors that are closely tied to fitness (Shackelford and Buss 1997; Dillon et al. 2015). Further, in a study of divorce using the standard cross-cultural sample — a database of 186 small-scale societies each coded for more than 2000 variables describing various aspects of typical behavior, beliefs, and environment — Betzig (1989) found that a handful of factors were associated with divorce, but most commonly infidelity and sterility. Both factors appear to cause

divorce in industrialized societies as well (e.g., Barber 2003), and both should also vary with socioecology. Economic opportunities were also associated with divorce in Betzig's (1989) study, a result similar to those in industrialized societies (e.g., Barber 2003). This mirrors trading-up territories as a cause of pair-bond dissolution in birds (Choudhury 1995), which should occur in environments with marked variation in territory quality.

Economic considerations are central to Quinlan and Quinlan's (2007) finding that subsistence complementarity was strongly related to pair-bond stability in a multivariate study of data from the standard cross-cultural sample. In other words, divorce is a curvilinear function of percent male contribution to subsistence. As shown in Fig. 3, when either males or females do the majority of subsistence work, there appears to be little reason to remain pair-bonded, though the reasons for this vary for the two non-complementary zones (Quinlan 2008). When females do the majority of the subsistence work, there may be no reason for males to stick around. When males do the majority of work, it may be that the work is geared toward "showing off" for potential future mates. Ellsworth et al. (2015) suggest their finding

Ecology of Pair-Bond Stability, Fig. 3 A schematic illustration of Quinlan and Quinlan's (2007) discovery of, and explanation for, a strong association between pair-

bond stability and subsistence complementarity in societies from the Standard Cross-Cultural Sample

of a latitudinal gradient in marital stability, but a lack of association with subsistence type may be due to latitudinal gradients in subsistence complementarity. Another possibility is that latitudinal gradients in pathogen distribution shape the fitness payoff for genetically diverse offspring, which could also lead to higher divorce rates (Low 1990).

Resource predictability is another ecological factor that has been hypothesized to lead to pair-bond instability. Weinrich (1977), for example, used evolutionary logic to ascribe contrasts in pair-bonding strategies among US ethnic groups as a function of income predictability. Studies of pair-bonding species might provide clues. For instance, Botero and Rubenstein (2012) found that environmental fluctuations and unpredictability were associated with divorce in a study of 163 bird species, suggesting that such flexibility in mating behavior may serve to minimize the negative fitness consequences associated with ecological crossovers – i.e., where the fitness payoffs for one mating strategy are drastically reduced with sudden, unpredictable environmental changes. Other studies of humans, however, suggest that there is not such a simple link between the two. For instance, Cohen (2014) found that divorce rates *decreased* in the USA during the Great Recession of 2008–2011, the most drastic economic crisis of the twenty-first century.

Conclusion

Human behavioral ecology brings evolutionary logic to bear on the problem of the ecology pair-bond stability. Most work has centered on mate desertion theory, and its emphasis is on the trade-off between mating and parenting in males. This perspective is limited, however, as the costs and benefits of mate desertion go beyond the immediate effects on current offspring survival and the probability of finding a new mate. Models with a broader scope need to be developed, models incorporating a wider range of costs and benefits.

Ecology of Paternal Investment

Melanie Dawn Douglass

Paternal care

Definition

The activity of expending time, energy, or resources on one's offspring

Introduction

One of the primary drivers of animal behavior is successful reproduction. In humans, as with all mammalian species, and most avian and fish species, this involves considerable time and effort engaging in parental care. This expenditure, which often poses a risk to the animal's own survival, was coined “parental investment” by Trivers (1972). For the majority of mammalian species, parental investment is primarily undertaken by females. However, humans exhibit biparental care; that is, care by both biological parents (Woodroff and Vincent 1994). Given the importance of parental care for physical and psychological well-being in humans, a considerable body of research has been conducted to explain the conditions under which biparental care develops and the proximal factors that maintain it.

Female-Dominated Care

Before looking at the factors that have led to biparental care in humans and other, largely non-mammalian, species, it is necessary to examine why female-dominant care is the norm for mammals. Even prior to conception, in many species,

females have a larger gametic investment, with female gametes being exponentially larger than male gametes and limited in number from birth (i.e., differential gametic potential). In all live breeders, reproductive potential is also limited by the length of the gestational period. For mammals, newborn young are wholly reliant on nourishment from their mothers, which often delays the onset of post-reproductive conception. In combination, these factors lead to a decreased reproductive potential in females. This has two consequences: at any given time, there are fewer females capable of reproducing, meaning that females can afford to be choosier during mate selection, and males face a quality or quantity dilemma, whether to care for present offspring or to focus on seeking out additional mates elsewhere. Moreover, for animals that breed internally, paternal investment puts the male at risk of cuckoldry. Indeed, recent advances in DNA analysis have shown that extra-pair paternity is much more common than previously assumed, even in species which were previously thought to be monogamous (e.g., Dillard 2016). For these reasons, therefore, biparental care is not adaptive for the majority of mammals. However, the opposite pattern is found in fish species, where the costs of parental investment are often much higher in females than in males (Balshine-Earn 1995; Clutton-Brock and Parker 1992). This shows that parental investment is largely dependent on the life course of the species under examination.

Environmental Factors

Just as with cooperative breeding, environmental factors can arise that make it not only adaptive, but necessary for biparental care to occur. Indeed, Markham et al. (1995) has posited that biparental care will only occur when environmental conditions necessitate. These conditions may take the form of extreme weather conditions (Mongolian gerbils), high predation rates (raptures versus passerine birds), or scarce resources (penguins). When such environmental pressures are present, the relative cost-to-benefit ratio of engaging in parental care is altered, such that failure to invest in offspring decreases

overall fitness, even though some fitness is lost by forgoing current reproductive opportunities. Another factor of importance is how altricial offspring are, as opposed to precocious; it is believed that this may be the main factor driving biparental care in humans (Cartwright 2016; Hrdy 2011). That is, human offspring, unlike the majority of living organisms, are wholly incapable of survival without care and are much more vulnerable to predation or injury than other mammalian species, most of whom are mobile within hours or days of birth. Humans also have a protracted development, such that they are not capable of any real degree of independence for more than a decade after birth. The combination of vulnerability and the extent of care required for human offspring to survive necessitates care by more than one individual.

Proximal Factors

A second explanation for the development of biparental care in humans is the proposal that it may have first arisen as an alternate mating strategy (Meynard et al. 2001). It is well-established that testosterone is positively related to aggression and negatively related to parental investment across species and sexes (e.g., Holecamp's Hyena Project). Subordinate males may find it particularly difficult to find a mate or hold a territory and may, therefore, choose to engage in cooperative parenting with a female who already has offspring, thereby gaining reproductive potential following successful rearing (Meynard et al. 2001). The advantage of the care-then-mate strategy may be that it decreases the risk of cuckoldry (Meynard et al. 2001). This shows that hormones and other psychobiological factors may be a proximate cause of parental investment decisions. In addition, research has indicated that the probability of future reproductive opportunities (e.g., mortality risk) and indicators of health of both offspring and mate also play a role in determining how much parental investment, if any, will occur (e.g., Laczi et al. 2017). This is because there is a certain degree of parent-child conflict inherent in parental investment; it is often in the child's best interest to receive more care than would be in the best interest of the parent(s).

Conclusion

Parental investment is dependent upon the life-course history and the environmental factors present in the reproductive environment. While the majority of animals engage in some form of parental investment, the extent of this investment will be dependent on the costs involved (i.e., to one's own survival/fecundity) and the likelihood that the offspring will survive and reproduce. For humans, recent research using an evolutionary game approach suggests that a high infant mortality rate resulted in the predominant reproductive strategy in humans being monogamous care, though extra-pair reproduction did occur (Alonso and Rodríguez 2017). However, despite decades of scientific inquiry, understanding of parental investment, especially in humans, remains limited. This is problematic given the importance of the family unit to well-being. It is, therefore, in our best interests to continue striving to understand the place of parental investment, including its ultimate and proximate causes, to our human family.

Synonyms

Economic deprivation; Financial distress; Financial pressure; Perceived income inequality

Definition

Economic hardship refers to psychological distress that results from a perception of relatively low economic resources (Barrera et al. 2001). Hardship is contrasted with poverty, which is simply the lack of economic resources. Economic hardship does not need to involve an actual lack of economic resources, but simply a perception of this deficit. Economic perceptions are heavily influenced by comparative processes (Kraus and Park 2014). Consequently, economic hardship is closely related to how one's economic resources

compare to others. Hardship is also related to *competitive disadvantage*, which describes when an individual is disadvantaged relative to competitors in hierarchical social structures. When one perceives themselves as having fewer resources compared to their competition – due to such factors as economic hardship – they may infer competitive disadvantage.

Introduction

Economic hardship describes a perceived lack of extrinsic resources, with resultant consequences for selection: Individuals with more resources generally tend to survive and reproduce more effectively. Individuals who possess greater resources are also more able to provide higher levels of parental investment, increasing the probability of genes being successfully transmitted to the next generation. Economic hardship may in part act as a barometer of competitive disadvantage indexed by the possession of extrinsic resources. Those who suffer from economic hardship – that is, those who perceive themselves to be competitively disadvantaged relative to others – likely engage in different patterns of conflict and cooperative behaviors. Conflict behaviors allow individuals to gain access to resources through nonconventional means. Cooperation is a tool that allows those experiencing economic hardship to receive resources from resource-rich individuals in an exchange, or as a form of insurance against poverty. We review these consequences of economic hardship in more detail below.

Conflict

As a result of experiencing economic hardship, an individual may believe that they are not able to gain sufficient resources through normative means (and thus perceive themselves to be competitively disadvantaged). Those who are competitively disadvantaged, still need resources to survive, attract mates, and ensure offspring survival. Therefore, they may decide to reduce their disadvantage by engaging in antisocial acts

against others in their environment (Wilson and Daly 1985). Through these acts, they may gain resources or status, and competitors may lose resources or status. In both cases, the antisocial actor's competitive disadvantage relative to the victim is reduced or eliminated, which may in turn reduce relative economic hardship and competitive disadvantage.

Wilson and Daly's (1985) conception of *young male syndrome* is a key example of the relationship between competitive disadvantage and antisocial conduct. Evidence clearly indicates that young men commit a disproportionate amount of antisocial and criminal acts. Wilson and Daly (1985) explain this cross-cultural fact by arguing that young males experience intense competition. Those who are competitively disadvantaged may turn to need-based risk-taking, such as antisocial behavior and crime, in an attempt to gain outcomes that may otherwise be unattainable through nonrisky or nonantisocial means. Economic inequality – that is, steep disparity between “haves” and “have nots” – has been robustly linked to increased risk-taking and crime, providing further evidence of the link between competitive disadvantage and conflict behaviors (reviewed in Daly 2016). Importantly, economic inequality is a much more robust predictor of conflict behaviors than is simple poverty, suggesting that competitive disadvantage (i.e., perceived economic hardship compared to others) is more important than simple lack of resources.

Cooperation

Based on the behaviors of contemporary hunter-gatherer societies, Gurven (2004) argued that many societies have a cultural bias toward helping the needy (i.e., those who are competitively disadvantaged). Evolutionary pressures have likely supported this development, although the relative contribution of different selection pressures to cooperation is still being debated (see Cooperation). For example, givers may provide resources to those experiencing economic hardship to get something else in return (reciprocal altruism), leading to increased fitness in the long run. Giving

to competitively disadvantaged individuals may also signal to other members of the society that givers have enough resources to survive *and* give away to others. Such giving may indicate that the giver holds higher relative position (social status) compared to those that have enough resources to survive but not enough give to others, with resultant positive survival and reproductive consequences. In a social game that measures cooperation, participants with higher intelligence scores were more likely to give resources to a public pool compared to those with lower intelligence scores (Millet and Dewitte 2007). The authors argued that intelligence is associated with a greater ability to acquire resources, and high-intelligence individuals signal this ability through cooperation.

Fear of economic hardship may have also influenced the evolution of cooperation. Cashdan (1985) posits that altruistic norms may have developed as a form of insurance against need. Individuals may invest resources into helping others with the expectation that they would in turn receive financial aid should they need it. Just like insurance, individuals often pay a small amount of their resources to a communal fund used to help those experiencing economic hardship. If others in their society do the same, these givers should expect that if they were to experience economic hardship, they would receive some of these communal funds. Thus, factors that would reduce their fitness through a loss of resources (even uncontrollable factors like natural disasters) would now not have as deep of an effect on them; they can rely on their neighbors to provide for them. In support of this hypothesis, Suleiman, Aharonov-Majar, and Luzon (2015) demonstrated in an experimental study that people are more likely to join groups and share resources when facing environmental risks (in this study, losses in a game of chance). Further evidence for the social insurance hypothesis comes from an examination of sub-Saharan African water resellers. Compared to households connected to water that do not resell water, those who do resell water were generally in a more precarious economic situation (Zuin et al. 2014). Many of these resellers, however, do not enter this business for financial reasons and may lose money by

engaging in water reselling. Instead, Zuin et al. (2014) argued they resell water with the expectation that buyers would help them if they were to need help in the future; facing economic hardship encouraged resellers to share water with others as a form of insurance against this hardship.

Conclusion

Economic hardship refers to the perception of a deficit of resources compared to others. Those who suffer from economic hardship are competitively disadvantaged, with resultant consequences for survival and reproduction. The perception of economic hardship may motivate individuals to adopt different behavioral strategies including both increased conflict behaviors and increased cooperation.

Economists and Evolutionary Psychology

Vincent Barnett
London, UK

Definition

Economics has traditionally been defined as a subject concerned with those aspects of human behavior that are involved in the application of scarce resources to produce, distribute, and consume goods and services for the satisfaction of human wants. However, evolutionary psychology has increased the scope for understanding the

“human behavior” component of economic activity by positing that the human brain contains a large number of evolved psychological mechanisms that play a key role in framing this economic behavior.

Introduction

Over the last two centuries or so, many economists have exhibited an ambiguous attitude towards psychology and evolution as disciplines, even while sometimes borrowing isolated concepts from them, but a few economists have embraced both of these subjects and fruitfully utilized them within the economist’s conventional remit.

The most well-known economist to do this was the American institutionalist Thorstein Veblen, but this entry will demonstrate that many other economists have attempted to import concepts from what can be called evolutionary psychology in its broadest meaning into their analyses. Moreover, less recognized is that evolutionary psychology itself has economics-related concepts embedded within in, which could be used to partially reformulate the basic principles of economics as a discipline, if such a reformulation was so desired.

This entry is structured as follows. It will first consider the work of one nineteenth-century and two twentieth-century economic thinkers who employed aspects of past incarnations of evolutionary psychology to a degree, Gabriel Tarde, Veblen, and F.A. Hayek, before it then examines the work of a number of contemporary economists who have employed a modern version of it more directly. Finally it will examine the implications of two central concepts developed by contemporary evolutionary psychologists for economic analysis: the existence of evolved cognitive architecture for social exchange, and the functioning of biological markets.

Gabriel Tarde (1843–1904)

Tarde has a direct link to the further development of Charles Darwin’s theory of evolution by natural selection as his work was actively considered by

James Baldwin, the initiator of the well-known Baldwin effect whereby learnt behavior is posited to become innate (Weber and Deprew 2007). Tarde was the author of *The Laws of Imitation* and he also wrote a book devoted to economic psychology. Tarde asserted that social evolution was composed of two basic elements, innovation and imitation, and the latter often involved a form of adaptation. Baldwin employed the concept of imitation to develop a theory of individual mental growth through imitation that led directly to the idea of organic selection or the Baldwin effect (Richards 1987, 470). Baldwin distinguished between social and psychological imitation, the latter providing the raw materials for learnt habits to become instinctive via organic selection, or what he called accommodations to the local environment.

The Baldwin effect is still controversial in the scientific literature, but it is a logically possible means for some psychological mechanisms to have evolved. Darwin posited that many new instincts evolved by means of random variations to preexisting ones, but he also allowed that habits could influence instincts (Darwin 1873, 418). This latter mechanism is conventionally interpreted as mistaken Lamarckism, but the Baldwin effect would be one way for it to occur through neo-Darwinian means.

Thorstein Veblen (1857–1929)

If the psychological mechanisms of evolutionary psychology are equated with the older concept of instinct, then Veblen's book *The Instinct of Workmanship and the State of the Industrial Arts* can be highlighted as the first major work by an economist to explicitly employ a version of evolutionary psychology (Veblen 1914). Here, Veblen distinguished between tropismatic urges, simple instincts, complex instincts, habits, and institutions, some of these concepts having equivalents in contemporary evolutionary psychology (Barnett 2017; Buss 2004). Veblen had obtained his initial understanding of psychology from four authors of the period, William James, William McDougall, C. Lloyd Morgan and Jacques Loeb, the first two of whom are embraced as pioneers by

today's evolutionary psychologists (Tooby and Cosmides 2005, 7), although Veblen developed his understanding of instinct in a unique way.

Veblen hypothesized the existence of a significant number of instincts including the workmanship instinct, the parental instinct, the predatory instinct, the emulation instinct, the beauty instinct, and the curiosity instinct, the latter generating in modern times the scientific spirit. One of Veblen's most significant innovations was to distinguish between simple and complex instincts; the latter being (in part) evolved structured combinations of simple instincts and other tropismatic urges. Veblen deployed these simple and complex instincts to explain how human behavior was driven by various teleological goals, to understand how different instincts could come into conflict or contaminate each other, and to explain how habits and institutions that had evolved on the cultural plain could act to modify and develop these instinctive proclivities.

Explicitly employing a version of the environment of evolutionary adaptedness concept (but without labeling it as such), Veblen located the origin of instincts as adaptive solutions to problems of survival and reproduction that had faced human beings across the Paleolithic period of prehistory, although he located the origin of the predatory instinct in *Homo sapiens* in a more recent period: alongside the Neolithic origins of agriculture and the concomitant processes of animal domestication (Barnett 2018).

Veblen explicitly championed the application of Darwin's theory to economics. In his article "Why is Economics not an Evolutionary Science?" Veblen advocated the employment of what he termed a post-Darwinian method of cumulative causation in economics, rather than the conventional utility maximization approach of mainstream economic theory. As he explained: "The economic life history of the individual is the cumulative process of adaptation of means to ends that cumulatively change as the process goes on, both the agent and his environment being at any point the outcome of the last process" (Veblen 1919 [1898], 74–75). He also implied that economic methodology should be rehabilitated using what he called modern anthropology, ethnology, psychology, and "the biological sciences proper."

One of the most well-known concepts that Veblen developed in his work was conspicuous consumption, or the purchase and display of extravagant products that were much more expensive than their basic equivalents. He argued that conspicuous consumption functioned as a status display mechanism and as a means to indicate social group membership; evolutionary psychologists would add that it also functions in relation to intrasexual competition as a means to attract mates.

Ever since Veblen, there has existed a group of institutionalist economists who have developed his legacy, but – ironically – Veblen’s most penetrating insight – that an understanding of economic behavior must be framed by means of an evolutionary conception of psychology – was discarded by most institutionalist economists on the mistaken assumption that Veblen’s instinct psychology quickly became out-of-date. In fact, it is the behaviorist critique of instinct psychology that is now recognized as mistaken.

F.A. Hayek (1899–1992)

Hayek is somewhat less recognized than Veblen as a contributor to an evolutionary understanding of psychology, but in *The Sensory Order: An Inquiry into the Foundations of Theoretical Psychology and Knowledge, Evolution, and Society*, Hayek did develop some themes that are also found in evolutionary psychology. For example, in the latter, he explained that: “our innate moral emotions and instincts were acquired in the hundreds of thousand years – probably half a million years – in which *Homo sapiens* lived in small hunting and gathering groups and developed a physiological constitution which governed [their] innate instincts” (Hayek 1983, 29). He also argued that cultural selection as a process was analogous to biological selection.

Hayek is one of the few economists to have written a substantial book on the workings of the human brain. In *The Sensory Order*, he argued that identifying basic human urges and drives was essential for an accurate explanation of purposive behavior (Hayek 1952a, 81). He proposed

as the central thesis of his book that sensory or mental qualities were not an attribute of individual physiological impulses, but that instead these qualities were determined by the system of connections by which the impulses were transmitted from neuron to neuron; it was the position of the impulse in the whole system of connections which distinguished it; and this system of connections was acquired both in the course of the development of the species (i.e., by evolution) and also in the individual’s own life-experience (Ibid., 53). This in turn required the development of a biological theory of the evolution of adaptive and purposive processes. Current understanding of neural networks is of course much more sophisticated than Hayek’s, but systematic interconnections are still a prominent feature of them (Nolte 1999, 18).

Elsewhere Hayek proposed the notion that: “all the ‘physical laws of production’ which we meet, e.g., in economics, are not physical laws in the sense of the physical sciences but people’s beliefs about what they can do” (Hayek 1952b, 31), implying that a main focus of economics should be on mental capacity. Moreover the objects of economic activity could, for Hayek, only be defined with reference to evolved human purpose and the terms of view that people held about particular commodities and money, i.e., through an evolutionary understanding of psychology. Hayek is one of the most well-known economists of the twentieth century but his work emphasizing the importance of the psychological foundations of economic behavior is sometimes unfairly overlooked.

Contemporary Economists

There are a number of contemporary economic thinkers who employ aspects of modern evolutionary psychology in varying degrees in their work, including Vernon Smith, Gad Saad, P.H. Rubin, Jason Potts, Nigel Nicholson, Stephen Lea, and others.

Gad Saad has focused much of his research on the evolutionary foundations of consumption and marketing (Saad 2007), for example,

explaining compulsive buying and other consumption-related addictions as maladaptive behaviors caused by the “misfiring” of evolved psychological mechanisms that have positive functions when deployed in the correct way and/or in the correct context. Geoffrey Miller has also considered evolutionary consumer psychology, in particular how costly signaling theory developed by evolutionary biologists can be applied to product branding and advertising techniques (Miller 2009).

Vernon Smith has imported the concept of ecological rationality, as elsewhere developed (Todd and Gigerenzer 2007), from evolutionary psychology to economics, defining it as relating to an ecological system that had emerged from both biological and cultural evolutionary processes (Smith 2008a, 36). Smith contrasted two different types of rationality that he termed constructivist as against ecological rationality. The former related to the conscious, deliberate, deductive processes that were conventionally believed to underlie human reason by economists. The latter related to the unconscious, automatic, neuropsychological processes that enabled human beings to function effectively without the employment of conscious constructivist reason (Smith 2003, 466–68).

However, Smith’s version is an adaptation: “*Ecological rationality* refers to emergent order in the form of practices, norms and rules governing action by individuals, groups and institutions that are part of our cultural and biological heritage, created by human interactions, but not by conscious human design” (Smith 2008b, 139). Emergent practices were seen as higher-order consequences of human interactions as structured by cultural and biological heritage, a form of nonconscious intelligence embodied in rules and traditions that had formed out of the “ancient history of human social interactions” (Smith 2003, 470).

Evolutionary psychologists have developed a parallel definition of ecological rationality which, while it overlaps with Smith’s definition, differs from it in some ways. Ecological rationality is defined by evolutionary psychologists as encompassing all the problem-focused

psychological mechanisms that have evolved in response to specific statistical regularities – ecological structure – that had been encountered in ancestral environments (Buss 2004, 377).

One important area where evolutionary psychology differs strongly from the assumptions of mainstream economics is sex differences. In this regard, Paul Rubin and Chris Paul have developed an evolutionary model of risk taking and risk aversion in relation to an individual’s age and sex: adolescent males are more risk seeking and mature males are more risk averse. Moreover, they posited that, in environments where only those males with incomes higher than a certain level (or with access to a certain level of resources) are attractive to females, noticeable sex differences in risk preferences would evolve (Rubin and Paul 1979). The wider consequences of this latter point are something that evolutionary psychologists understand well, but most economists do not, naively assuming that the risk profile and men and women are identical, or at least very similar.

In fact, men and women (on average across large numbers of individuals) exhibit a very different attitude to risk, one indication of this being that young men are much more likely to engage in physical altercations with each other than young women (Byrnes et al. 1999). This difference in attitude to risk has consequences for how men and women choose to make financial and investment decisions across their lives and with respect to their offspring. It also has important consequences for understanding differences in rationality in general terms when comparing men and women. If women and men have evolved (in some respects) different psychological mechanisms for responding to distinct life-tasks and social situations, then this is likely to have important consequences for the attempt to understand male and female economic behavior.

Another subfield of economics where evolutionary psychology has fruitfully been applied is the nature of money. Stephen Lea has developed an evolutionary account of purchasing and shopping behavior and also of money motivation, distinguishing between “tool theories” and “drug theories” of money. In the former, money is

understood as simply a means to an end and its value is seen as purely instrumental; in the latter, money is conceived in addition as plugging into ancient evolved motivational systems, and as being desired for more that it can deliver in purely material terms. Lea argued in turn that any “tool theory” was incomplete and had to be supplemented by a version of the “drug theory,” the ancient motivations involved being evolved psychological mechanisms relating to both reciprocal altruism and object play (Lea and Webley 2006). Following on from Lea, Vincent Barnett has suggested that money most likely first came into being as the solution to the “cheater” problem of the potential for social exchange partners involved in reciprocal altruism to defect at a future date (Barnett 2015).

One area of economic analysis is particularly well-suited for the application of concepts from evolutionary psychology: understanding the organizational structure of companies and business management systems. Various concepts developed by evolutionary psychologists such as dominance hierarchies, status striving, cooperative alliances and collective behavior, the consequences of group size, the evolution of organizational structures in prehistory, and others have been applied to assist in understanding how company organization and personnel management operate.

For example, some companies modeling their structure around the “family, village, and tribe” system of organization that operated in human hunter-gatherer prehistory have been identified (Nicholson 1998). Elsewhere, how individuals attempt to bias periodic tournaments for advancement (e.g., company promotion opportunities) in their favor so that their own power is preserved/advanced has been identified. This can be accomplished by denigrating opponents and exaggerating their own achievements for example, in contrast to what has been specified as the false theory of the prevalence of a meritocracy within business structures.

Finally, Jason Potts has developed an evolutionary theory of *homo aëconomicus* by positing that the nomadic lifestyle of our distant ancestors had important consequences for the cognitive

adaptations that evolved, in particular, the fact that resource-availability in the African savanna was only semistable over both time and space: nomadism is here defined as a behavioral strategy within a space. Potts then linked these evolved nomadic instincts with their hypothesized modern behavioral descendants such as business entrepreneurship and innovation (Potts 2003).

Social Exchange

A key concept developed by evolutionary psychologists of direct relevance to economics is that “the enduring presence of social exchange interactions among our ancestors has selected for cognitive mechanisms that are specialized for reasoning about social exchange” (Cosmides and Tooby 2005, 585). These psychological mechanisms, if they do exist, “would ground economics in the evolutionary and cognitive sciences, cross-connecting economics to the rest of the natural sciences” (Ibid.). Obviously, this is a controversial claim for economists to accept, as it would mean that their subject would have to be at least partly reconstituted, but it is certainly one worth exploring in more detail.

Deferred cases of exchange – or reciprocal altruism – take place among all human beings while they are adhering to an implicit and accepted set of rules, or an implied form of social contract, e.g., those relating to the nature of the reciprocity, to the value of the items or services being exchanged, and to cheater detection. It is this set of rules that evolutionary psychologists assert are present as specialized in-built features of the human mind. As evidence that such psychological mechanisms do actually exist, the fact that people routinely choose to cooperate with others rather than defect, sometimes even when defection gives a higher payoff, is cited, as well as empirical findings that individuals do not follow the standard precepts of rational choice theory when making related calculations (Ibid., 618). In addition, the fact that children develop social exchange abilities at an early age is also cited as evidence that this capacity is in-built.

This type of evidence, while it has very definite value, is not conclusive: it is logically possible that social exchange skills are acquired by learning at an early age, although the mechanism for this learning would need to be clearly specified. It is also possible to suggest that social exchange skills are simply one set of skills provided by a more general cognitive system. In response to the latter suggestion, the argument is made that social exchange skills are very specific and natural selection would therefore favor the evolution of a set of specialized mechanisms devoted to this task.

If human beings do possess evolved cognitive architecture for social exchange, then this could have significant consequences for many aspects of economic behavior, such as how traders make buy/sell calculations and how financial investment decisions are made. When money is being exchanged for a good or service, then the individual involved is invariably making some type of mental calculation regarding their preference for having the good or service rather than retaining the money. This calculation would necessarily employ some of the social exchange architecture hypothesized as existing by evolutionary psychologists.

For instance, the notion that the cognitive architecture of social exchange contains mechanisms for evaluating the relative worth of goods and services is an idea that is of direct relevance to economics. In hunter-gatherer societies, food items obtained by individuals were shared amongst others on a regular basis. The hypothesis is that this process, over the very long run, facilitated the evolution of psychological mechanisms for evaluating the relative value of specific items, e.g., food or other supplies. If one individual with a supply of meat gives a portion of this meat to someone else at a given point in time, then this other individual will be obligated to return the exchange at a future date.

Suppose further that at this future date the second individual reciprocates when they have a supply of fruit, but how much fruit was the meat previously received worth? There needs to be a shared method of evaluation so that the pair can agree that a fair exchange has been made. The hypothesis is that cognitive architecture would

evolve that facilitated such judgments as to what a fair exchange would be in such instances, relating perhaps to labor/time expended; or, more likely, *Homo* cognitive capacity in this regard is an evolution of previously-evolved great ape capacity, as reciprocity behavior has been detected in chimpanzees and monkeys (Cosmides and Tooby 2005, 589). This would mean that human beings have an innate sense of the relative value of certain goods and services, something that would be of definite significance for economics.

Biological Markets

For evolutionary psychologists, the gamete market for a reproductive partner is the most important market that any animal participates in, including human beings: this hypothesis is at odds with some of the central tenets of mainstream economics. Although some economists have analyzed the marriage market, the principles used to analyze this market are different from the principles used by evolutionary psychologists to analyze the gamete market. In the gamete market, there is a central asymmetry between the value of what the male animal provides (sperms) and what the female provides (ova), which has consequences for the associated behavior of the participants. Economists do not fully recognize the significance of the biology involved and the associated evolved psychology, instead emphasizing the economic gains from marriage and financial issues such as the costs of raising children.

One reason why the gamete market is central for evolutionary psychologists is that the associated psychological mechanisms that have evolved to deal with behavior related to it have significant consequences for other areas of behavior as well. In addition, the individualistic conception of personal utility maximization used by economists as a foundation for understanding behavior contradicts the evolutionary psychologist's use of inclusive fitness (or close family interest) and kinship relationships as a foundation for their analyses, the latter being linked to the gamete market. The evolutionary biologist's assertion that all animals

have both selfish and altruistic traits also contradicts the more narrow view of individual self-interest used by many economists.

The evolutionary approach can be widened to create the more general concept of “biological markets,” where animal “traders” exchange biological and other commodities (e.g., nuptial gifts, nectar) and services (e.g., alarm calls, shelter) for mutual benefit. Biological markets are characterized by competition within trader classes by contest or outbidding, preference for partner value in reproduction, conflict over the exchange value of goods as the law of supply and demand operates, and mechanisms for determining the composition of trading groups (Noe and Hammerstein 1995). Biological markets encompass mating markets (the gamete market), mutualism between members of different species, and also cooperation among conspecifics.

The “biological markets” model is in contrast with the marriage market model presented by economists such as Gary Becker, which focuses on the allocation and distribution of resources within marriage and also on chosen partner characteristics (Becker 1973). Bizarrely for evolutionary psychologists, economists do not consider the biological factors involved, assuming that both sexes behave in the same way in their mating decision-making, as if their biology was identical. The impact of sex differences on behavior is perhaps the most significant difference in the underlying assumptions of economics and evolutionary psychology: both subjects cannot be correct. The fairly well-documented case of sex differences in spatial ability – males perform better in most tasks, except for female advantage in object-location memory – is a standard example in the literature (Puts et al. 2007, 334), but the consequences of these type of differences for economic behavior have not properly been considered by economists.

Conclusion

Ever since Tarde and Veblen, economists have had an ambiguous relationship with evolutionary accounts of psychology. A good example of this

ambiguity is Hayek. Even though he explicitly undertook a detailed study of brain processes for his book *The Sensory Order* and explicitly highlighted that economic laws should be conceived at least in part in psychological terms, most of his well-known works in pure economics such as *The Pure Theory of Capital* contain hardly any consideration of psychology, let alone of evolutionary psychology. This apparent contradiction can perhaps be explained in part by the significant degree of inertia in the conventional content of economics and the difficulty in Hayek’s time of going against the grain vis-à-vis the use of a Veblen-style instinct psychology in an era of behaviorism.

A similar phenomenon can be found in the work of Henry Sidgwick, a late-nineteenth-century economist and author of *The Principles of Political Economy*. Sidgwick explicitly considered Darwin’s work and recognized the importance of instincts to understanding human behavior in an article on the theory of evolution (Sidgwick 2000 [1876], 22), but he then virtually ignored instincts and evolution across his main economic output, as if economic behavior occurred in a realm entirely divorced from evolutionary influence.

However, in the more recent period, various economists have successfully employed evolutionary accounts of psychology in their work, as have been considered above. In addition, two basic concepts of evolutionary psychology discussed here – social exchange architecture and the gamete market – are of direct relevance to developing new foundations for a subject that might tentatively be called evolutionary economic psychology (EEP). EEP would place center-stage an understanding of how economic behavior is framed both by evolved cognitive architecture and sex differences in cognition.

For example, conspicuous consumption of luxury items as a signal is, at least to a degree, interpreted differently by men and women. Women interpret the display more in terms of the indicated resource-giving potential of the man who owns the item, whereas men interpret the display more as a test of the purchasing judgment of the woman who owns the item, although both

sexes see multiple other meanings as well. As another example, it can be hypothesized that successful traders must possess sophisticated cognitive social exchange architecture, perhaps in a more developed form than is found in the average individual. This would not mean that social learning processes would have been unimportant to these successful traders, only that such learning would have been partly framed by preexisting social exchange architecture.

One final existential problem might seem to face the economist who wants to incorporate evolutionary psychology into their work. If evolutionary psychology is everything that it claims to be, such as providing the means to understand the cognitive foundations to all social exchange behavior, then why not dispense with economics entirely and become an evolutionary psychologist? One plausible answer is that economics does ask some distinct questions that differ from those of conventional evolutionary psychology, and hence it offers space to develop original contributions that might not get produced under the latter subject's standard remit. What is certain is that the crossover between economics and evolutionary psychology will continue to be fruitfully mined in the future.

Edward Hagen

Kristen Syme
Washington State University, Vancouver, WA,
USA

Definition

Edward Hagen is a biological anthropologist who specializes in the evolution of depression, self-harm, psychoactive drug use, among other topics.

Introduction

Edward Hagen is a Professor of Anthropology at Washington State University where he has taught since 2007. He received his Ph.D. in Anthropology from UC Santa Barbara in 1999 under the supervision of John Tooby and took a postdoc in

Peter Hammerstein's group at the Institute for Theoretical Biology, Humboldt University, Berlin, from 2001 to 2007. Hagen has published on numerous topics in evolutionary psychological theory, but his work predominately centers on evolutionary approaches to noninfectious disease, particularly mental health. He is best known for his evolutionary theoretical research on depression and psychoactive drug use. His publications defending the field of evolutionary psychology against its critics are also widely cited.

The Bargaining Model of Depression, Self-Harm, and Suicidal Behavior

Most major depressions are caused by adversity, but most people who experience adversity suffer sadness, grief, or other negative emotions, but not major depression. Major depression is nevertheless common in adults of all ages. Hagen has developed theoretical models rooted in costly signaling theory in an attempt to explain the function of major depression (Hagen 1999, 2002, 2003) as well as nonlethal suicidal behavior and self-harm in an evolutionary framework (Hagen et al. 2008; Syme et al. 2016).

In many cases, individuals can adequately respond to adversity with little help from others. In other cases, however, individuals need help, yet, due to *conflicts of interest*, help might not always be forthcoming. Informed by game theoretic models, Hagen posited that both depression and suicidal behaviors could effectively serve as bargaining strategies that function to elicit support from social partners (e.g., genetic kin or a mate) who are reluctant to provide it. According to these models, the symptoms of depression and/or self-harm reduce or eliminate an individual's investment in joint cooperative endeavors that benefit her social partners as a strategy to compel them to provide her with more help. In other words, the behavioral correlates of depression and suicidality are evolved mechanisms that function to protest exploitation.

Hagen first outlined the bargaining model of depression in the context of postpartum depression (PPD), which serves as a case for the model

more generally. The bargaining model of PPD proposes that depression during this vulnerable period might be an adaptation that arises when a new mother is suffering a fitness cost (Hagen 1999, 2002). Low mood, anhedonia, and psychomotor retardation, among other symptoms in effect, function to reduce or eliminate the mother's investment in her infant such that social others who might share a concern for the infant (e.g., the father, mother's kin) would have to increase their share of investment in correspondence to their stake in the infant's survival. This theory accounts for the major risk factors of PPD, namely, marital discord; a lack of social support, particularly from the father; and poor infant health (see Hagen 1999 for an exhaustive list of sources). For most of human evolution, these conditions would have severely impeded the fitness of the mother and her infant. If the mother does not receive the support she needs, then she might eliminate investment entirely resulting in infant death at which point she can redirect investment toward mating and future offspring.

More broadly, depression is a bargaining strategy that emerges when cooperation imposes a net cost, but constraints make defection impossible. For instance, social partners might monopolize a resource (e.g., a mating opportunity). The depressed individual goes "on strike" by withholding their investment in the cooperative enterprise. Furthermore, the depressed individual sends a costly signal that informs the social partner of their true valuation of the endeavor, which is low due to the fact that he or she is not receiving their fair share of the benefits (Hagen 2002).

Hagen and Rosenstrom (2016) developed the unified bargaining model of depression and aggression. They argue that when social partners are imposing high fitness costs for little reward, those who are physically strong will be more aggressive – a confrontational strategy – to negotiate, while those who are physically weak will be more depressive, a withdrawing strategy. Since almost all males are more physically formidable than almost all females, this model might help explain the sex difference in depression, and Hagen and Rosenstrom found evidence to support this hypothesis.

Hagen applied the bargaining model to self-harm and suicidal behavior (Hagen et al. 2008; Syme et al. 2016). As with the bargaining model of depression, according to Hagen, self-inflicted harm could act as a means of signaling social need. The goal of some suicidal behavior, according to this model, is not death, but rather this behavior represents a last resort to elicit aid in otherwise hopeless situations. The bargaining model of suicidal behavior was supported in a test of two evolutionary models of lethal and nonlethal suicidal behavior against 53 cultures in the ethnographic record. The study found that across cultures suicidal behavior frequently occurred in response to social conflicts that posed a fitness threat to the victim (e.g., forced marriage); the victim was often powerless relative to those whom they were in conflict with; and, a victim who survived a suicide attempt could influence others to act in accordance with his or her valid interests (e.g., preventing a forced marriage) (Syme et al. 2016).

Research on Psychoactive Drug Use

In a series of papers, Hagen and colleagues investigated tobacco and cannabis use among Aka foragers in the Congo Basin (Roulette et al. 2014, 2016a, b). In a 2014 paper, the researchers reported the results of a test of a novel evolutionary hypothesis that recreational use of tobacco can defend human hosts against parasitic infection. The researchers write, "Plants have evolved an enormous variety of toxins to deter herbivores, and herbivores have co-evolved to use plant toxins to defend against their own parasites, a phenomenon referred to as self-medication, zoopharmacognosy, or pharmacophagy" (Roulette et al. 2014). Hagen and colleagues argue not that humans evolved to consume tobacco or any other specific plant toxin, but instead that humans, like other vertebrates, evolved mechanisms for regulating the consumption of psychoactive plant toxins (Hagen et al. 2009, 2013; Sullivan et al. 2008). The researchers found evidence to support the hypothesis that tobacco is protective against helminthic infection. Among the 260 Aka males

in the sample, there was a negative correlation between cotinine, a nicotine metabolite, as measured in saliva and worm burden as measured in stool samples. Moreover, they found that treating helminthes with a commercial anthelmintic reduced cotinine concentration 2 weeks following administration compared to controls, suggesting that tobacco use covaries with the degree of worm burden. These findings among others support the hypothesis that humans use tobacco as well as other psychoactive plant toxins to defend against parasitic infection. In a separate study, Hagen and colleagues found a negative correlation between THC levels and parasitic infection among the Aka (Roulette et al. 2016b).

Hagen and colleagues have also investigated sex differences in drug use (Roulette et al. 2016a; Hagen et al. 2016). Globally, females use drugs recreationally less often than males, which many have attributed to gender inequality. Hagen et al. (2016) found that cross-nationally women's total fertility rate and measures of gender inequality are independently associated with female tobacco smoking prevalence. Throughout most of human evolution and in modern natural fertility populations, females spend most of their reproductive years pregnant or lactating. Thus, fetal protection is a likely source of women's lower drug use prevalence. This evidences differential benefits in the use of plant neurotoxins for the purposes of pharmacophagy.

Defense of Evolutionary Psychology

Hagen is an adamant defender of evolutionary psychology (EP) against critics who attack the field on political and philosophical grounds (Hagen 2005, 2014). He eschews the pervasive delusion among the critics of EP that humans will be moral and selfless if we imagine them to be that way in favor of a more realistic view of human nature based on evidence and facts. To summarize Hagen's standpoint, the most pragmatic means of limiting behaviors such as infanticide, exploitation, sexual assault, suicide, and other harmful acts is to identify the human propensity toward these behaviors and the environmental

circumstances that are most likely to trigger them (Hagen 2005). Since the laws of the physical world govern the mind, pretending otherwise could never produce real social change.

Other Research

Hagen in conjunction with colleagues has published on a wide array of topics in evolutionary psychology including pregnancy cravings and aversions (Placek and Hagen 2013, 2015, Placek et al. 2017), indirect aggression and informational warfare (Hess and Hagen 2006; Hess et al. 2010), parental investment (Hagen et al. 2001; Hagen et al. 2006), game theory (Hagen and Hammerstein 2006), and music and dance as coalitional signaling (Hagen and Bryant 2003; Hagen and Hammerstein 2009).

Effect of Birth Control on Women's Preferences

S. Craig Roberts

[Contraceptive pill](#); [Hormonal contraception](#); [Oral contraception](#)

Definition

Birth control relates to any method of preventing conception while engaging in sexual intercourse. This can include avoiding intercourse while the woman is fertile (e.g., rhythm method), pre-ejaculatory withdrawal, and barrier methods (e.g., condom, uterine cap) which prevent sperm from reaching the egg. So far as we know, choice of these methods has no effect on women's mate preference. This entry is instead concerned with modern hormonal methods of birth control (especially the oral contraceptive pill) which achieve contraceptive function by manipulating women's reproductive physiology and function.

Introduction

Birth control (BC) is one of the most successful and widely used of all medical interventions. More than one-fifth of women of reproductive age (15–49) and in a relationship use the “pill”, injectable or implant BC methods across the world, and these rates are typically even higher among younger and unmarried women (United Nations 2015). BC has undoubtedly improved women's quality of life, giving women control over their reproductive lives and enabling them to postpone childbearing and pursue other important goals. Nonetheless, given the prevalence of use in younger women, at a life stage where most are seeking to establish life-long partnerships and begin families, any unintended effect on the success of those family units warrants rigorous attention. There is accumulating evidence that use of BC may indeed have just such effects, by exerting subtle changes in mate preferences.

Hormonal Contraceptives and Women's Mate Preferences

Some previous studies suggest that women's preferences for male traits exhibit an increased periovulatory preference for traits that appear to signal high mate quality (e.g., Roberts and Little 2008). It is argued that stronger preference for such traits as facial masculinity when conception probability is high suggests a mechanism by which women maximize quality of mating partners (Penton-Voak et al. 1999). If these cyclic shifts are shaped by changing hormonal levels associated with ovulation, then they should be absent in BC users.

Consistent with this suggestion, Little et al. (2002) showed that a stronger preference for facial masculinity in attractiveness judgments for short-term than long-term partners, which was present in normally cycling women at ovulation, was absent in women using BC. Another study showed that users of BC have weaker changes in masculinity preferences for both faces and voices (Feinberg et al. 2008). Similarly, while normally cycling women show increased ovulatory

preference for the odors of symmetrical over asymmetrical men, this preference is absent in BC users (Thornhill and Gangestad 1999). These studies indicate that BC use is associated with reduced demand for male characteristics that ovulating women typically display.

Other studies show that BC users have qualitatively different preferences compared with non-users. For example, they appear to have stronger preferences for health, which is also characteristic of women with high progesterone levels, such as during the luteal phase of the menstrual cycle or in pregnancy (Jones et al. 2005). Furthermore, in contrast to normally cycling women who were more attracted to odors of men who are genetically dissimilar at genes in the major histocompatibility complex (MHC), BC users display the opposite trend, preferring odors of more MHC-similar men (Wedekind et al. 1995). Among vertebrates, preferences for MHC-dissimilarity are thought to be usually favored because this may increase offspring heterozygosity and in turn to enhance the ability to fight infectious diseases.

Although such studies indicate that BC may influence women's mate preferences, it might be argued that differences between users and non-users are simply a product of between-group behavioral or attitudinal characteristics, rather than a direct consequence of BC use. To address such concerns, Roberts et al. (2008) used a longitudinal design to compare odor preferences for MHC-similar/dissimilar men before, and 3 months after, initiating BC use. Consistent with a direct BC effect, women's preferences shifted after initiating BC towards MHC-similar odors, compared with a nonuser control group tested across the same 3-month interval. This study provided the first direct evidence of a causal link between BC use and disruption of partner preferences.

One other study has demonstrated a similar effect. From a sample of the same women tested in Roberts et al.'s (2008) study, preferences for facial masculinity were also tested using the same design. Whereas there was little change in the control group, women's preference for masculinity was reduced after initiating BC use, and this effect was observed in male but not female faces, suggesting a mate choice-specific effect rather

than one that affects general face perception (Little et al. 2013). Not only this, but in a separate sample, it was found that, in women who used BC when the couple met, the male partners had more masculine faces compared with partners of women who were not using BC when the couple met (Little et al. 2013). Although this latter result could be due to between-group differences, it raises the possibility that changes in mate preferences could have real-life effects on actual mate choice.

Implications of Altered Mate Preferences

The clearest implications of altered mate preference choice due BC come from the studies on MHC-correlated mate preferences. If preferences of nonusers are typically for MHC-dissimilar partners but BC use brings about a preference for MHC-similarity (Roberts et al. 2008), then we might expect couples who meet while the woman is using BC to be comparatively MHC-similar. One possible consequence of this would be direct health consequences for any offspring due to their lower heterozygosity. Such consequences could include higher rates of miscarriage (Beydoun and Saftlas 2005) and lower resistance to infectious diseases in offspring (Carrington et al. 1999). Furthermore, reduced heterozygosity and hence perceived poorer health may additionally influence the perceived attractiveness of offspring (Roberts et al. 2005).

It is also likely that alteration of mate preference, for any given preferred trait, will directly influence a woman's attraction towards her partner when she changes BC use. Imagine, for example, a woman who is using BC when she meets her partner, and presumably finds him very attractive. If she ceases BC use, then both her hormonal levels and her preferences will revert to their normally cycling states, and she may subsequently no longer find her partner as attractive as she did. Alternatively, if the same woman began BC use *after* meeting her partner, she might experience the reverse pattern of changes, but ultimately with the same kind of outcome: a preference *now* that is different (or noncongruent) to what it *was* when

she met her partner. Both these examples have been captured in what has been termed the *congruency hypothesis* for BC effects on women's sexual desire for, and satisfaction with, their partner (Roberts et al. 2013).

The first evidence for the congruency hypothesis comes from a comparison of approximately 2500 women who were BC users or nonusers when they met their male partner, but who were all nonusers when they were surveyed. Although women who were using BC when they began their relationship were more satisfied with their partner's level of support, they reported lower attraction towards him and lower sexual satisfaction with him (Roberts et al. 2012). In another sample of about 350 couples, women's sexual satisfaction was higher if their current BC use was congruent with that at the time they met their partner, compared to noncongruent women, although BC congruency did not affect levels of nonsexual satisfaction (for a replication, see Russell et al. 2014), nor either kind of satisfaction among the male partners (Roberts et al. 2014). Similarly, levels of sexual but not other kinds of jealousy were higher in women if their current and previous use of BC was congruent (Cobey et al. 2013). Other studies that simply compare BC users and nonusers report comparable differences in not just sexual jealousy (Cobey et al. 2011) but also other related aspects of mate-guarding behavior (Welling et al. 2012). Ultimately, such sexual dissatisfaction and mistrust may have consequences on relationship survival; indeed, Roberts et al. (2012) found that in couples who had subsequently separated, women who more likely to have initiated the separation if they met their partner while using BC.

Conclusion

There is growing evidence that use of hormonal contraceptives influences women's mate preferences and has consequences on subsequent relationship satisfaction. Cross-sectional studies may be strongly influenced by between-group differences, and more longitudinal studies are needed in the future.

[Domain-specific reasoning about dominance hierarchies](#)

Definition

The effect of social hierarchy and status position on the evolution and implementation of social reasoning abilities.

Introduction

Sociality, the formation of social groups by a species, is often seen as an evolved solution to some of life's most basic problems, such as how to obtain food, how to successfully reproduce and care for young, and how to avoid predation long enough for these prior concerns to be issues at all. While helping to solve many of these problems, sociality also presents a unique challenge: how are limited resources, such as food, to be distributed among group members? In response, many social species, including humans, developed social hierarchies wherein higher-status individuals typically have priority access to resources. Therefore, while sociality and social hierarchy helped solve some evolutionary problems, they themselves produced unique evolutionary pressures. In this context, Cummins (1998) hypothesized that key components of reasoning developed in response to the demands of competing and cooperating within social groups and social hierarchies. More precisely, she argued that domain-specific reasoning capacities (e.g., cheater detection) evolved to recognize and respond to the social rules concerning necessary (obligatory or prohibited) and permissible behaviors found in social hierarchies. Evolutionary, behavioral, and neuroimaging evidence in support of these claims is reviewed as well as investigations and literature suggesting the need for further research.

Hierarchies, Evolution, and Social Reasoning

Put simply, a social hierarchy means that in social groups certain individuals maintain regular and priority access to key resources, such as food and mates (Cummins 2006). In turn, these high-

status individuals are more likely to survive and are more likely to have offspring (Ellis 1995). Importantly, in many species, most notably primates, social hierarchy is not stable, nor is it simply a matter of pure physical dominance (i.e., physical size or strength) (Harcourt and de Waal 1992). In this context, survival and reproductive success depends on the amount of time one is able to spend in positions of relatively higher status, which in turn depends on a number of nonphysical factors (Altman et al. 1996). In this regard, it is likely that natural selection would favor psychological and neurological mechanisms to effectively navigate status hierarchies. Evidence in primates suggests that key among these mechanisms are a collection of social reasoning abilities, including the capacity (i) to learn the rules around necessary (obligatory or prohibited) and permissible behaviors, (ii) to detect and remember those who violate these rules (cheaters), (iii) to form and monitor reciprocal relationships (cooperation and reciprocity), and (iv) to read and understand the intentions of others (theory of mind) (for a review see Cummins 2000). In other words, the better you are at these abilities, the more likely you are to successfully navigate the social hierarchy, achieve and maintain high-status, and thus survive and reproduce. In this way, sociality and status hierarchies are seen to provide evolutionary pressures and context for the development of foundational social reasoning capacities in many social species.

Hierarchies and Social Reasoning in Humans

Far from being a primitive feature of nonhuman social species, social status and hierarchy appear to be universal across human cultures (Brown 1991). Indeed, while the signs and impact of status and hierarchy are easily identified in many cultures (e.g., income inequality, caste systems), hierarchy and status also appear to be among the first and most stable characteristics seen in human peer groups (Strayer and Trudel 1984). For example, the development and recognition of status hierarchies are found in children as young as two

and continue to play a major role in social structure throughout the life-span (Frankel and Arbel 1980). Moreover, the ability to understand and report on the structure of a social hierarchy appears to develop in children well before the ability to describe similarly complex content in nonsocial domains (Smith 1988). This developmental trajectory may suggest that humans are predisposed to attend to and develop social skills in reference to social hierarchies. This sensitivity to social status is even found at the neuroendocrine (e.g., cortisol, adrenalin, testosterone) and physiological levels (e.g., heart rate, blood pressure; Knight and Mehta 2014). For example, when allowed to retaliate against an aggressor of lower status, heart rate, blood pressure, and cortisol indices, initially elevated by the frustration of the situation, return to baseline levels. In contrast, if the aggressor is a higher-status individual, these stress indices remain at their original, frustration-induced, levels (Hokanson and Shetler 1961). In other words, social hierarchy appears to be an integral part of human societal structure, developing early and impacting not only our cognition but our physiology as well.

While humans and nonhuman primates differ in many regards, it is clear that human social structures were, and are, subject to many of the same hierarchy pressures seen in nonhuman primates. In this context, it is unsurprising that many of the same social reasoning abilities used by primates to successfully navigate hierarchical social structures are seen, and expanded upon, in humans. Indeed, decades of research demonstrates that, just like nonhuman primates, human's success at navigating social structures depends on the capacity (i) to learn the rules around necessary (obligatory or prohibited) and permissible behaviors, (ii) to detect and remember those who violate these rules (cheaters), (iii) to form and monitor reciprocal relationships (cooperation and reciprocity), and (iv) to read and understand the intentions of others (theory of mind) (see Cummins 2000 for review). While each of these skillsets is seen as important, much research has focused on people's ability to (i) learn social rules and (ii) detect cheaters, as these skills are not only seen as foundational for more advanced social

reasoning skills (e.g., reciprocity, and theory of mind) but also appear to be intimately linked to one another.

In countless studies across numerous disciplines, researchers have consistently demonstrated that humans appear to be more effective at reasoning in some domains than others, with one of the largest and most well-established differences being seen in social reasoning. Most often this difference is studied in regard to the deontic-indicative distinction. Deontic reasoning is concerned with social rules or what is permitted, obligated, and forbidden. When engaged in deontic reasoning, individuals appear to spontaneously look for and identify violations of these social rules. Importantly, in both functional and cognitive terms, social hierarchies can be conceptualized as a collection of specific social rules imposed on lower-status individuals by those of higher status. In this way, deontic reasoning is directly tied to many of the social constraints (rules) seen in social hierarchies. Indicative reasoning, in contrast, is concerned with what is true or false and triggers a confirmation-seeking strategy. Importantly, although indicative reasoning can be related to social content, it is not related to social rules. Notably, humans consistently perform significantly better on deontic tasks (60–90% correct on deontic tasks vs 10–30% correct on indicative versions of the same tasks; Cummins 2000). In other words, people perform consistently and systematically better on social reasoning tasks when they entail social rules concerning what is permitted, obligated, or forbidden. While abundantly clear in adulthood, this difference also appears to be present in early development. For example, by age 3, children appear to preferentially check for and determine whether a social rule has been violated and are able give specific reasons why a behavior represents a rule violation (Cummins 1996; Harris and Nuñez 1996). Importantly, mirroring what is seen in adults, this skill does not appear to transfer to nonsocial problems of similar complexity. This advantage for social rule-based reasoning is seen at even younger ages as well. At 16 months, children are already preferentially noticing and attending to violations of social rules (Cummins

1999a), and by 24 months, they use social rules to justify their behavior (Dunn 1988). Overall, these results seem to indicate that humans are uniquely skilled at social rule-based reasoning, that this advantage develops early, and that it continues to impact reasoning throughout the life-span.

Importantly, the broader literature on this social reasoning advantage, and more specifically the deontic effect, is not without controversy (see Cummins 2000 for a brief review). Indeed, over the years, numerous theories have been developed to explain the deontic effect, with some arguing in-line with the domain-specific process already introduced, while others advocate a more domain-general approach. For example, some argue that the deontic effect is simply due to familiarity with social content rather than any unique or evolved advantage for social reasoning. Despite decades of inquiry, consensus around the best-fitting theory is still lacking.

Regardless of this debate, a crucial component seen in the potential social reasoning advantage is the tendency to spontaneously check for rule violations when considering social rules. While violation-detection is equally appropriate of other types of reasoning, such as evaluating whether a statement is true, it appears to be rarely used outside of situations focused on social rules. In this regard, detecting and remembering those who (intentionally) violate rules, cheaters, is seen as a crucial component to forming and enforcing the rules necessary for even a basic level of sociality. While cheater detection is obviously important for social rules in general, this bias may be particularly important in reference to status hierarchies. Specifically, in order to maintain priority access to resources, high-status individuals often need to maintain the status quo, which entails checking for, remembering, and penalizing cheaters. While there is a wealth of examples to support the impact of status on cheater detection in nonhuman primates, evidence is currently equivocal in humans. Specifically, while there is some evidence to suggest that individuals are more likely to check for and remember cheaters of relatively lower status (Cummins 1999b; Mealey et al. 1996), more recent studies have failed to replicate these results (Barclay and Lalumière

2006; Mehl and Buchner 2008; Buchner et al. 2009). In this regard, two aspects are important to note. First, in all of these studies, status was manipulated in a relatively narrow fashion focused on occupation or income. In contrast to this, literature and research on social status in humans indicate that an individual position in the social hierarchy is determined by a variety of connected, yet independent, constructs, such as power, socioeconomic status, dominance, prestige, influence, and leadership (Blader and Chen 2014). Further complicating this picture, while social status is often discussed as a dispositional attribute, it is also highly situational, such that an individual may be of high status in one environment (e.g., friend group or family) but low status in another (e.g., occupation). Second, numerous studies indicate that cheater detection is influenced by a host of individual and situational variables, such as subjective importance of detecting cheaters (Chiappe et al. 2004) and the relative number of cheaters (Barclay 2008), meaning that cheater detection is not a static phenomenon. Thus, more research is needed to untangle the potential impact of status on cheater detection in humans, with a special focus on the numerous ways human status can be determined and conceptualized.

Evolution of a Neural Architecture for Social Reasoning

A key concept in Cummins proposal is that evolutionary pressures not only helped to shape key aspects of social reasoning but that a similar and mirrored development occurred in neuroanatomy. In her original manuscript, four points were addressed to support this idea. First, the development and role of the neocortex compared to the evolutionarily older structures found in the limbic system. In general, the limbic system is responsible for relatively basic socio-emotional functions, such sexual behavior, aggression, and emotion. In contrast, the neocortex, is responsible for higher-level cognitive and social functions, such as thought and language. The variation in function and the later development of the neocortex are seen as evidence that higher-level social functions

evolved in a commensurate fashion with specific and evolutionarily newer neural architectures.

Second, prefrontal lobe syndrome in humans and bilateral prefrontal ablations in primates suggest that there are specific neural substrates responsible for crucial components of social reasoning. In prefrontal lobe syndrome, bilateral damage to the ventromedial prefrontal cortex produces impairment in socio-emotional stimuli, typically without producing similar impairments in broader intellectual functioning (Damasio 1994). In primates, bilateral prefrontal ablations of the ventromedial or dorsolateral prefrontal cortices result in similarly dramatic changes in social functioning, with these changes not typically seen from damage to other cortical areas (Cummins 1998).

Third, autism, a neurodevelopmental disorder, is characterized by selective impairment in the social domain. Specifically, individuals with autism find it difficult or impossible to reason, especially automatically, about the mental states or beliefs of other individuals, which makes it exceedingly difficult for them to engage in cooperative or reciprocal social interactions (Baron-Cohen 1995). Despite this, however, individuals with autism typically do not display impairments in other nonsocial domains of cognitive functioning. Mirroring prefrontal lobe syndrome and the bilateral prefrontal ablations, this selective impairment of social reasoning suggests a unique and separable neural architecture for social reasoning.

Lastly, in primates, the neocortex ratio, the relative volume of the neocortex to the rest of the brain, correlates positively with social group size (Dunbar 1993). This suggests that larger groups, and thus more complex forms of sociality (due to the increased number of relationships), require greater cognitive resources. Moreover, given the evolutionary trajectory of the neocortex, this suggests that more complex forms of sociality developed alongside the necessary neural architecture (i.e., larger neocortex).

More recent advances in neuroimaging also appear to detail a neural architecture adapted for social reasoning (Barbey et al. 2009). Indeed, converging results from numerous studies suggest that the lateral prefrontal cortex enables the representation of evolutionarily adaptive social rules,

with each of its three major subsections supporting particular types of reasoning necessary for various degrees of sociality. Specifically, the ventrolateral prefrontal cortex is tied to reasoning about necessary actions (rules about obligatory or prohibited behavior), the dorsolateral prefrontal cortex is involved in reasoning about possible (permissible) actions, and the anterolateral prefrontal cortex is recruited for higher-order reasoning that incorporates both necessary and possible actions. Importantly, research also demonstrates that the lateral prefrontal cortex initially evolved from the ventrolateral prefrontal cortex, followed by the dorsolateral and then the anterolateral regions. Given the functional significance of each area, this developmental trajectory makes evolutionary sense. The foundation for basic sociality is being able to create, understand, and enforce necessary (obligatory and prohibited) social rules, which are instantiated in the ventrolateral prefrontal cortex, which evolved first. Following this, social rules around permissible behaviors enable a greater range in possible behaviors and thus more complex social relationships. Mirroring this trajectory, these abilities are found in the dorsolateral prefrontal cortex, which developed second, after the ventrolateral regions. Finally, representing and reflecting on rules governing both necessary and permissible behaviors foster even more complex social relationships, with these abilities being facilitated by the dorsolateral prefrontal cortex, which developed last. Thus, current data suggests that social reasoning around rules may have evolved in a commensurate fashion with specific neural architectures supporting particular abilities.

Recent data also suggests that social status may play an important role in the development and function of this architecture. In a hierarchy, rules created and enforced by members of a higher social status represent necessary rules that an individual of lower rank must follow. Given this it is not surprising that areas for identifying others' social status are anatomically connected to ventrolateral prefrontal regions, which are crucial for reasoning about necessary rules. This link between status and necessary rules was supported by a recent study by Marsh et al. (2009), which

demonstrated selective recruitment of the ventrolateral prefrontal cortex when processing status poses for high-status individuals. Future studies leveraging various conceptualizations of human status hierarchies could provide further clarity about the role of social status on the development and function of social reasoning neural architecture.

Importantly, however, it must be noted that advances in neuroimaging also demonstrate that social reasoning and status hierarchies are not exclusively dependent on areas in the lateral prefrontal cortex. Indeed, countless studies have implicated a host of diverse areas in social reasoning and social hierarchy, including the parahippocampal cortex, the ventral striatum, the sensorimotor cortex, the supplementary motor area, the amygdala, the anterior insula, the anterior cingulate, the inferior parietal lobe, and the inferior parietal sulcus (Pornpattananangkul et al. 2014). Moreover, the lateral prefrontal cortex and its subsections are not solely implicated in reasoning about social concepts. For example, the ventrolateral prefrontal cortex is implicated in motor activity, such as walking, as well as the ability to detect and retain spatial information from visual cues. Thus, while there is strong evidence to suggest a neural architecture for social reasoning, it remains unclear whether this network was evolutionarily adapted specifically and uniquely for reasoning about social content such as status hierarchies and cheating.

Conclusion

Evidence to date provides equivocal support for much of Cummins' (1998) hypothesis that key components of reasoning developed in response to the demands of competing and cooperating within social groups and social hierarchies. While there are certainly results and data from evolutionary, behavioral, and neuroimaging contexts supporting key aspects of this hypothesis, questions remain. Indeed, there are inconsistencies in and failures to replicate key results, an important debate around the interpretation of the deontic effect, and a need for more nuanced and

detailed investigation into the neural architectures supporting social reasoning. Future research can provide clarity in many of these areas through continued replication attempts, acknowledgement and investigation into the numerous ways social status is determined in human hierarchies, and continued consideration of competing theories.

Effect on Attachment

Caregiving; Quality of attachment

Definition

Attachment is the strong, affectionate bond we feel for individuals who provide pleasure when we interact with them and comfort by their proximity when under stress.

Introduction

Attachment is something that many creatures develop with those that provide care for them. Typically, infants form attachments by the second half of their first year of life. Infants will form an

attachment to individuals that respond to their needs. These needs can be items such as food and shelter, or they can be more emotional as in providing comfort when we are in a stressful situation. While most infants will form an attachment with their parents, this may not always be the case.

Attachment Based on Food or Touch

It was thought by behaviorists that a mother would satisfy an infant's hunger, which was a primary drive, and this is what leads to attachment. Because of this feeding, the infant would prefer the comfort and closeness of their particular caregiver. Harlow and Zimmerman (1959) put this idea to the test. They provided baby monkeys with surrogate mothers, one made of wire that provided the baby monkey with food and the other wrapped in terry cloth. What they found was that even though the wire mother provided food, the baby monkeys preferred to cling to the terry cloth mother. This shows that just because one provides food, the tactile sense of touch is extremely important when forming an attachment.

Styles of Attachment

Mary Ainsworth and her colleagues (1978) were pioneers in the domain of attachment styles. They created the strange situation so that they could objectively observe the infant-parent attachment style. In the strange situation, infants are allowed to play in a room while the caregiver is present. A stranger would enter the room and the caregiver would exit the room. They monitored the stranger attempting to comfort the infant as well as the interaction of the infant with the caregiver once they returned to the room. Ainsworth and colleagues found a few different styles of attachment. The most common was called secure attachment. In this style of attachment, infants used the caregiver as a secure base and explore the area. When the caregiver left the room, the infant became visibly upset. The stranger was unable to calm the infant; however, when the caregiver returned, the infant would actively seek them out and crying

was reduced quickly. The infants were upset because the caregiver was absent and preferred them to the stranger. The next attachment style found was avoidant attachment. Infants with this attachment style were not very responsive to the parent, while they were present and not usually distressed when the parent left, reacted to the stranger in a similar fashion as they did to the parent, and were slow to greet the parent when they returned. When the parent would pick them up, oftentimes they would fail to cling to the parent. The third attachment style is known as resistant attachment. These infants sought closeness with the parent and would not explore the area. When the parent left, they would become visibly distressed. When the parent returned, they would blend clinginess and resistive behavior. Infants appeared to be angry with the parent as they would often hit or push away from them when picked up. Also of note, these infants were not easily calmed as they would continue to cry even though the parent had returned. The fourth and final attachment style found is disorganized attachment. Infants in this attachment style showed a multitude of confused and contradictory behaviors when the caregiver returned to the room. Infants would sometimes look away while being held and show their disorientation with a dazed facial expression, and a few would begin to cry without warning after they had been calmed. These four styles of attachment were major discoveries and have helped shape the way we view infant-parent interactions.

Effects of Opportunities for Attachment

René Spitz (1945; Spitz and Wolf 1946) observed what happened to infants when they did not have an opportunity to produce a close bond with a caregiver. He observed infants that were given up by their mothers and institutionalized. These infants shared a nurse with at least seven other babies, and their pre-separation happy demeanors turned into more withdrawn demeanors after separation. When a consistent caregiver did not replace the mother, the infants lost weight and had difficulty sleeping. Tizard and Rees (1975) followed adopted children who were placed in homes after

the age of 4. They found that many of these children were able to form their first attachment as late as the ages of 4 to 6 years. However, these children did tend to display social and emotional problems. Some children excessively sought out adult attention, while others would become overly friendly toward unfamiliar adults and peers.

Conclusion

From previous research it is easy to see that forming an early attachment is extremely important for humans. Daycare may be easy for parents, but it could prove to be harmful for kids if there is a large ratio of children to those taking care of them. The children could become more depressed and withdrawn or start aggressively seeking adult attention. Some parents may feel that they have no choice in the matter and are obligated to go back to work. It is possible that these children could form more of an attachment with the individual taking care of them at daycare than with their parent. It does appear that as long as the parent creates sufficient comforting, physical contact, they can form an attachment with the child. The main cause for concern is to make sure that the child has an opportunity to form an attachment, either with their primary caregiver or have a consistent alternative.

Definition

John Bowlby argued that attachment, beyond the main biological function of increasing infants' chances of survival, is important for psychological development. A robust association has subsequently been established between children's attachment quality/organization and psychological development, particularly as regards socio-emotional functioning (e.g., internalizing and externalizing behavior problems, social competence), with secure attachment linked to favorable development and insecure attachment to increased risk for suboptimal development. Important research questions pertain to the factors that mediate (e.g., internal working models, emotion regulation, executive

functioning) and moderate (e.g., attachment quality to other adults, child temperament, factors related to social context) the relation between attachment quality and subsequent development. Another question is whether variations in attachment quality are specifically important for particular aspects of development or constituting a protective vs. risk factor in general. Yet another one is to what extent, and for which developmental outcomes, variations in children's attachment quality contribute to developmental outcomes when other aspects of caregiving that may covary with caregiver sensitivity are taken into account.

Introduction

John Bowlby, the founder of attachment theory (see ► [“John Bowlby: Pioneer of Attachment Theory”](#)), contested the theories of attachment available at the time since they defined attachment was secondary to other processes (e.g., “drives” and feeding, see ► [“Psychodynamic Foundations”](#)). Bowlby therefore devoted a great effort into finding an alternative and scientifically sound explanation for attachment, and he eventually formulated the core tenets of attachment theory by drawing from multiple scientific disciplines, including ethology, cybernetics, and cognitive psychology (see ► [“Evolutionary Foundations of the Attachment System and Its Functions”](#)). This work includes the conceptualization of the attachment system as a behavioral control system with a specific function of continuously monitoring and maintaining proximity to caregivers, retained through evolution as it served an adaptive function of increasing chances of survival against predators and other natural dangers (see ► [“Infant Survival”](#) and ► [“Offspring–Parent Attachment”](#)).

Bowlby was also convinced that children develop individual variations in attachment quality, depending on how consistently available the caregiver(s) have been and how effectively the caregiver(s) have responded to the children's signals (i.e., caregiver sensitivity). He was moreover convinced, in line with psychodynamic object

relation theories (see ► [“Psychodynamic Foundations”](#)), that children's attachment quality is important for subsequent psychological development and mental health; “what is believed to be essential for mental health is that the infant and young child should experience a warm, intimate and continuous relationship with his mother (or permanent mother-substitute) in which both find satisfaction and enjoyment” (Bowlby 1997, 1982, p. xi–xii).

However, Bowlby lacked an empirical method for examining individual variations in attachment quality and could therefore neither “systematize” these differences nor conduct detailed mapping of relations to personality development. He instead examined effects of child-caregiver separations, which he regarded as a possible pathogen for children's personality development (i.e., a form of trauma) and which were readily observable in the post-World War era, and, for example, found that delinquent and aggressive children had experienced more frequent early separations from their caregivers (Bowlby 1944). In explaining such findings, Bowlby argued that “the young child's hunger for his mother's love and presence is as great as his hunger for food, and in consequence, her absence inevitably generates a powerful sense of loss and anger. . . loss of mother-figure, either by itself or in combination with other variables yet to be identified, is capable of generating responses that are of the greatest interest to psychopathology.” (Bowlby 1997, 1982, p. xiii).

Bowlby was therefore grateful to his close collaborator Mary Ainsworth who, by conducting extensive naturalistic observations of children's attachment development and developing a laboratory observation procedure for examining individual differences in attachment quality (the strange situation procedure (SSP)), discovered three organized patterns of attachment together with relational antecedents (Ainsworth et al. 1978; see ► [“Individual Variations in Attachment”](#)). Briefly, the three patterns are secure attachment, associated with sensitive caregiving and denoting a flexible ability to use the caregiver as a secure base from which to explore the environment and as a safe haven to return to for

comfort (see ► [“Secure Attachment”](#)); insecure-avoidant attachment, associated with rejecting and intrusive caregiving and denoting relative minimization in the expression of attachment behaviors when distressed; and insecure-ambivalent/resistant attachment, associated with inconsistent caregiver sensitivity and denoting relative maximization of expressions of attachment behaviors coupled with anger/ambivalence and difficulties being soothed by the caregiver’s overtures (see ► [“Organized-Insecure Attachment”](#)).

Mary Main (a student of Ainsworth) later discovered a fourth attachment category, insecure-disorganized/disoriented attachment, denoted by an inability to maintain any of the three organized patterns following activation of the attachment system (Main and Solomon 1986; see ► [“Disorganized Attachment and Reactive Attachment Disorder”](#)). Disorganized attachment is behaviorally manifested in, for example, odd, inexplicable, and simultaneous and sequentially contradictory behaviors in relation to the caregiver (Main and Solomon 1990), and is relationally predicted by frightening/frightened and dissociative caregiver behaviors (e.g., Schuengel et al. 1999). However, disorganized *behaviors* have also been predicted by temporary overstress (Granqvist et al. 2016) and neurological vulnerability (e.g., Forslund et al. 2016b; Padrón et al. 2014). A disorganizing relational *history* can therefore not be inferred merely from observations of disorganized *behaviors*.

The “patterns of attachment” and the SSP-enabled systematic assessment of relations between individual variations in attachment quality/organization and subsequent development. This research was further strengthened by “the move to the level of representation,” which enabled examination of individual variations in attachment in older children, adolescents, and adults using representational measures in which participants are interviewed about attachment-related situations and experiences (Main et al. 1985; for research in adults, see ► [“Adult Attachment”](#)). Research examining effects of variations in quality/organization of attachment was largely in its cradle at the end of Bowlby’s active career, but he noted two general insecure socio-

emotional patterns; “on the one hand a tendency to make excessive demands on others and to be anxious and angry when they are not met. . . and, on the other, a blockage in the capacity to make deep relationships” (Bowlby 1997, 1982, p. xiv). In delineating the problems yet to be solved, Bowlby rhetorically asked, “. . .how is each pattern related to subsequent personality development and health?” (Bowlby 1997, 1982, p. 331). The work pertaining to this question, which has largely been undertaken after Bowlby’s retirement and termed the “competence hypothesis” (van IJzendoorn and Sagi-Schwarz 2008), is the focus of the current discussion.

Elaboration of Bowlby’s Notions

Environmental programming of the attachment system and goodness of fit between its early programming and the later environment.

Bowlby argued that the attachment behavioral system is moderately stable and, within limits, open to learning from experience for adaptive functioning in children’s particular environments. Although Bowlby emphasized the benefits of the system’s flexibility, he also highlighted its downsides; “. . .a design that permits of modification according to environment is likely to result in equipment that is better adapted and more efficient in its workings than equipment based on a general purpose and fixed design can ever be; although with modifiability goes also the risk of curious twists of development. . .” (Bowlby 1997, 1982, p. 46). Using machines and cars as metaphors, Bowlby argued that no system can be programmed to suit every environment equally well; a car that is constructed (i.e., programmed) to suit the streets of London is hardly as adaptive in difficult countryside terrain (and vice versa). Thus, if the attachment system becomes programmed to function adaptively within a certain environment (aiding survival and reproductive success), it may be inefficient if it needs to operate in a different environment. Bowlby argued that such understanding would be of importance for the understanding of psychopathology (Bowlby 1997, 1982).

Applied to the “insecure patterns,” avoidant attachment may, for example, be adaptive for a child growing up in an environment wherein the caregiver(s) do not have the ability to respond sensitively. By minimizing expressions of attachment behaviors, and thereby not taxing the caregiver, the child may decrease the risk of further rejection (Main 1981) and, in evolutionary terms, the risk of being abandoned (Simpson and Belsky 2008). However, the “insecure strategies,” which are regarded as less flexible than secure attachment, may result in lower relationship quality and maladjustment when children grow older and form relationships beyond their immediate family context, for example, with peers and romantic partners. Hence, links between variations in attachment quality and psychosocial maladjustment may indicate a suboptimal fit between the early calibration of the attachment system and the environments in which children later operate (cf., “goodness of fit”). As such, secure attachment (i.e., expecting others to be available and responsive) may in fact be disadvantageous in some environments.

Secure attachment, which is the most frequent pattern across cultures, has from a developmental psychology perspective tended to be regarded as “normative,” as the “primary strategy,” and as the “optimal” calibration of the attachment system, with the insecure patterns regarded as suboptimal compromises (van IJzendoorn and Sagi-Schwartz 2008). For example, Main (1990) argued, following Bowlby’s reasoning, that the insecure patterns are psychological adjustments representing a gradual shift of attentional process (i.e., psychological defenses; see ► “[Psychodynamic Foundations](#)”) away from the baseline (i.e., secure attachment), necessitated by suboptimal responses from the caregiver in order to protect the infant from anxiety and contextually maladaptive behaviors.

Evolutionary psychologists have taken another stance, arguing that there is no primary strategy or “optimal” programming of the attachment system. According to this line of reasoning, there have been multiple evolutionary environments of adaptedness (EEAs), and the patterns of attachment may constitute various programs that are

triggered by different environments, wherefore no pattern of attachment should be considered more or less optimal (Simpson and Belsky 2008). The experience of physical abuse (linked to disorganized attachment) has, for example, been linked to expertise in identifying anger in other’s facial emotional expressions, arguably adaptive in these children’s immediate environment (Pollak et al. 2009). Naturally, if there were no advantages with “insecure” attachment in any contexts, it would be difficult to account for why approximately 40% of children and adults are insecure (with cross-cultural and contextual variations; van IJzendoorn and Sagi-Schwartz 2008). Evolutionary perspectives are however only partially considered in the literature, as the predominant position has been a more standard developmental/clinical psychology perspective.

Internal working models of self and others as the mediator between the environmental programming of the attachment system and psycho-social development. Bowlby (1973) emphasized, drawing from artificial intelligence theory (e.g., Craik 1943; Young 1964), that individual variations in attachment-related experiences are manifested in cognitive-affective representations of self and others which he termed internal working models (IWMs) (see Bretherton and Munholland 2008). The IWMs are thought to include expectations of others’ behaviors in relation to the self and the availability of others (particularly in attachment-related situations), as well as expectations on the self and its effectiveness in affecting the environment (including others). Importantly, Bowlby argued that IWMs of self and other are complementary as the child gets to know him/herself as a person through how (s)he is responded to by the caregiver.

Drawing from information processing and memory theories, Bowlby also argued that experiences of insensitive caregiving lead to the creation of incoherent (or multiple) IWMs, whereby the later emerging explicit (conscious, declarative) layer of the IWMs differs from the implicit (unconscious, procedural) layer. Thus incoherence stems, in Bowlby’s view, from the usage of psychological defenses, such as defensive exclusion, to protect the individual against anxiety

(Bowlby 1973; see also ► “[Psychodynamic Foundations](#)”). Importantly, Bowlby stressed that once IWMs are formed, they will guide children’s attention, behavior, and displays of emotion in future attachment-related situations (with the caregiver and others), and children therefore become active cocreators of their subsequent experiences.

In other words, Bowlby regarded the IWMs as a (partially) mediating factor between variations in attachment quality/organization and later functioning and development. The workings of the IWMs have often been inferred from the different patterns of behavior shown by children in attachment measures (i.e., the SSP). However, Bowlby’s claim has also received empirical support from, for example, eye-tracking research, showing that secure children attentionally expect (other) caregivers to respond sensitively to distressed children, whereas insecure children expect caregivers to respond insensitively (e.g., Johnson et al. 2010).

Empirical Research on the Association Between Attachment Quality and Developmental Outcomes

Since attachment theory is at its core a relational theory, a particularly large body of research has examined attachment quality in relation to socio-emotional functioning, as indicated by broad indices of social adaptation (e.g., social competence) as well as by distinct socio-emotional competences (e.g., emotion regulation).

Individual variations in attachment quality and organization in relation to broad indices of social adaptation. A series of meta-analyses have recently demonstrated significant and robust links (of small-to-moderate magnitudes) between attachment security and several broad domains of socio-emotional functioning. First, secure attachment has been linked to lower levels of internalizing behavior problems (e.g., anxiety, sadness, fearfulness, withdrawal; Groh et al. 2012). Second, secure children have been found to show lower levels of externalizing behavior problems (e.g., aggression, conduct problems;

Fearon et al. 2010). Third, secure children have also been found to be higher in social competence (e.g., peer acceptance/rejection, popularity, prosociality; Groh et al. 2014). The meta-analyses found that the associations between attachment quality and externalizing behavior problems and social competence were stronger than with internalizing behavior problems. However, examination of internalizing behavior problems may be particularly difficult since these problems are not as readily observable.

The meta-analyses moreover highlighted insecure-avoidant attachment as the pattern most strongly associated with internalizing behavior problems and disorganized attachment as the one most strongly associated with externalizing behavior problems. Importantly, associations between attachment quality and psychosocial adjustment have been obtained by parent ratings, teacher ratings, observations, and children’s self-reports (e.g., Bohlin et al. 2000). In sum, these findings support the competence hypothesis (van IJzendoorn and Sagi-Schwartz 2008). However, the magnitude of the effects are “only” small to moderate, suggesting that the strength of the associations may, in part, be dependent on interactions with other variables conveying risk or protection (see section on moderators, below).

Individual variations in attachment quality and organization in relation to specific socio-emotional competencies. Socio-emotional competence includes multiple distinct abilities (e.g., Saarni 1999), which have been grouped into three general abilities: emotion identification, emotion understanding, and emotion regulation (Colle and Giudice 2011). The subsequent selective review follows this structure with the addition of empathy. Conflicting findings have been reported, and more research is warranted in relation to each of these components, but a general pattern is emerging.

Several studies have reported links between attachment and the ability to identify facial emotional expressions in others. For example, Steele, Steele, and Croft (2008) found that school-aged children who had been coded as secure in infancy were better at identifying facial emotional expressions. Forslund et al. (2016a) moreover found a

generally diminished ability to identify facial emotional expressions in children with disorganized attachment representations, and Peltola et al. (2015) found that infants who were later classified as disorganized in the SSP lacked an age-typical attentional bias toward fearful faces. Effects of attachment on facial emotional expressions have been argued to stem from the importance of facial emotional interactions between children and their caregivers in the interactions leading to the formation of attachment (see Forslund et al. 2016a).

Several studies have also linked individual variations in attachment quality and organization to emotion understanding. For example, Barone and Lionetti (2012) found a diminished ability to understand emotions in preschoolers with disorganized attachment representations. Moreover, Laible and Thompson (1998) reported a higher ability to understand emotions in securely attached preschoolers, particularly for negative emotions. These findings have been discussed in the context of caregiver(s) being of special importance in children's early learning about emotions, and the process of forming attachments has even been termed emotion socialization (De Oliveira et al. 2004).

Lastly, multiple studies have reported links between attachment quality and emotional reactivity and regulation, as measured in overt behavior as well as in physiological responsivity. For example, Colle and Giudice (2011) found that children with secure attachment representations reported higher knowledge of adaptive emotion regulation strategies, with a linear effect indicating the least developed knowledge in disorganized children. Using parental reports, Contreras et al. (2000) also found more constructive coping mechanisms in secure children. Moreover, Nachmias et al. (1996), using laboratory tasks designed to trigger the fear system, found higher levels of constructive coping (e.g., social referencing, affective sharing) in secure children. Infants classified as secure have also been found to show lower levels of negative emotionality as toddlers, to be less oppositional, and to show more positive affect in relation to their caregivers in laboratory problem-solving situations and free play sessions (Matas et al. 1978).

As regards physiological responding, studies have reported heightened cortisol reactivity in insecure children in both the SSP and other situations designed to induce stress, though results have been conflicting regarding the insecure pattern(s) driving the effect. For example, whereas some studies have found elevated cortisol reactivity in resistant children (e.g., Luijk et al. 2010; Spangler and Schieche 1998), other studies have reported elevated cortisol reactivity in disorganized children (Hertsgaard et al. 1995; Spangler and Grossman 1993). Yet other studies have suggested that the relation may depend on an interaction with temperament, with elevated cortisol reactivity seen specifically in insecure infants who are *also* temperamentally inhibited (e.g., Nachmias et al. 1996; Spangler and Schieche 1994). Caregiver presence has also been found to buffer against or prevent cortisol elevations for secure children in situations designed to elicit fear (e.g., Nachmias et al. 1996; Spangler and Grossman 1993), and securely attached infants have been found to show lower cortisol levels than insecure children during adaptation to childcare settings (Ahnert et al. 2004).

Attachment quality and organization have also been associated with empathy. For example, Kestenbaum et al. (1989) found that secure children responded more empathically to a distressed peer and were rated as more empathic (see also Van der Mark et al. 2002). Panfile and Laible (2012), who also found a positive association between secure attachment and empathy, further found that this association was mediated by secure children's better emotion regulation and lower levels of negative emotionality. Indeed, becoming overwhelmed by negative emotionality (i.e., "personal distress") in relation to others' displays of distress is thought to compromise empathic responding. In this vein, disorganized children have been found to react with aggression toward cues of distress in others (Main and Goldwyn 1984), and disorganized attachment representations have been linked with an increase in callous unemotional traits in middle childhood (Bohlin et al. 2012).

Individual variations in attachment quality in relation to cognitive development. Attachment quality has also been linked to children's

cognitive development and intelligence (IQ). For example, Matas et al. (1978) found that secure children were more persistent and effective in problem-solving situations. Similarly, attachment security has been linked to children's executive functioning (EF; inhibitory control, working memory/updating, and set shifting; Miyake and Friedman 2012), concurrently (e.g., Bohlin et al. 2012; Forslund et al. 2016b), as well as prospectively (Bernier et al. 2012). Children experiencing prolonged separations from their main attachment figure due to the attachment figure working overseas have also been found to show impeded EF development (Hewage et al. 2011). Attachment security has also been found to predict higher school engagement via low attentional impulsivity and higher self-control (Drake et al. 2014). Attachment security in infancy has also been prospectively linked to IQ in preschool (van IJzendoorn and van Vliet-Visser 1988), and caregiver sensitivity has been found to predict children's general cognitive development (Lemelin et al. 2006).

Important Research Questions Regarding the Link Between Variations in Attachment Quality and Subsequent Development

As described above, empirical research has established a robust link between inter-individual variations in attachment quality and subsequent development, in line with Bowlby's hypothesis. There are however, as elaborated below, multiple remaining questions.

The specificity of individual variations in attachment in relation to developmental outcomes and the need for developmental integration

It is at present unclear whether systematic variations in attachment quality and organization should be viewed as important for specific aspects of children's development, or as a general risk vs. protective factor for adaptive/maladaptive development. One reason for this ambiguity is that most of the research undertaken to date has

investigated attachment quality in relation to only one or a few aspects of children's development at a time. For example, levels of externalizing and internalizing behavior problems and social competence may often covary, and research examining whether attachment quality is *specifically* associated with any of these domains of social adaptation would therefore need to control for the other domains.

As an illuminating example, interest has grown in disorganized attachment as a possible pathway to attention-deficit/hyperactivity disorder (ADHD), with concurrent as well as longitudinal associations reported (e.g., Pinto et al. 2006). However, disorganization is robustly associated with externalizing behavior problems such as oppositional defiance, which are highly comorbid with ADHD symptoms. The association between disorganized attachment and ADHD symptoms may therefore depend on a primary association between disorganization and externalizing behavior problems which causes a secondary elevation in ratings of ADHD symptoms. Indeed, examining disorganization in relation to both ADHD symptoms and conduct problems, and accounting for their overlap, Forslund et al. (2016b) found a specific association between disorganization and conduct problems but not between disorganization and ADHD symptoms.

Second, few studies have examined whether attachment quality contributes to different developmental outcomes when accounting for the role of various caregiver behaviors that may correlate with caregiver sensitivity and child attachment and in of itself constitute predictors of the pertinent developmental outcomes. For example, caregivers who are sensitive (the primary predictor of secure attachment) may also tend to be good at cognitive scaffolding (pedagogical support), which is an important predictor of children's development of executive functions. As such, research examining whether attachment quality per se is important for children's EF development should account for the role of caregiver's scaffolding. More studies examining (I) the specificity of links between attachment quality and different developmental outcomes and (II) which developmental outcomes attachment is predictive of beyond factors covarying with

caregiver sensitivity are clearly needed for developmental integration.

Factor(s) Mediating the Association Between Attachment Quality and Developmental Outcomes

Bowlby's (1997, 1982) notion of IWMs as a mediator is still popular, and the importance of IWMs has been acknowledged by scholars outside the attachment field, for example, in relation to conduct problems (Dodge and Pettit 2003). However, theorizing and empirical research have seen multiple proposals of alternative and/or complementary mediators, some of which overlap theoretically and/or are construed on different levels of analysis (i.e., on a level affecting the conditions for children's learning, or as influencing children's development of specific competencies).

Learning conditions as mediators

van IJzendoorn et al. (1995) reviewed and discussed four different hypotheses regarding learning conditions. First, according to the "attachment-teaching hypothesis" (cf., Fonagy and Campbell's [2015] *epistemic trust* idea), children's attachment quality may influence the caregiver's ability to teach their children, through attachment quality affecting how much resources children can devote to learning. That is, insecure children may have to devote more resources to attachment-related aspects of situations, consequently limiting the resources that remain for learning. Second, the "attachment-exploration hypothesis" (cf., Aber and Allen [1987] on *Readiness to Learn*) proposes that attachment quality might affect children's own ability to learn from the environment through effecting their exploration. According to this hypothesis, secure children, who are thought to have internalized a model of their caregivers as available if danger should arise (i.e., felt security), may be more free to explore the environment and learn from it. Third, according to the "social network hypothesis," secure children may develop more frequent, harmonious, and stimulating social relationships from which they can learn adaptive skills, with insecure children thought to be hampered by

defensive processes and anxiety. Fourth, according to the "attachment-cooperation hypothesis," secure children may be more cooperative with others as they may be less defensive and anxious.

Further, similar to the attachment-teaching/epistemic trust hypothesis, attachment quality may affect internalization of parental norms, with secure children found to heed parent's directives more in situations of do and don't (Kochanska 1995). Possibly related to several of these hypotheses, attachment quality may affect further development through effects on the stress response system, with increased stress reactivity possibly hampering insecure children's ability to explore on their own as well as their ability to learn from others.

Specific competencies as mediators

Regarding attachment quality and the development of specific competencies, the various patterns of attachment have been conceptualized as different strategies for emotion regulation, with secure attachment thought to facilitate flexible and open emotional communication (Cassidy 1994; Mikulincer et al. 2003). Moreover, children's EF has been proposed as a possible mediator, for example in relation to externalizing behavior problems, with disorganization and insecurity hypothesized to impede EF development (Fearon et al. 2010; see also Bernier et al. 2012). In line with Bowlby's account, attachment-related experiences and memories have also been discussed as potentially influencing social information processing (e.g., hostile attributional biases, Crick and Dodge 1994).

Research to date has not examined multiple proposed mediators simultaneously, and it is therefore unclear whether any one mediational hypothesis should be regarded as superior to the others. Indeed, it is also possible that attachment quality influences children's development through effects on multiple mediating factors simultaneously, for example influencing both children's exploration, their caregiver's ability to teach them, and their development of distinct competencies. More research is clearly needed to disambiguate these questions.

Factors Moderating the Link Between Attachment Quality and Developmental Outcomes

From the onset, Bowlby (1997, 1982) reasoned that attachment quality might assert its influence through interactions with other variables. Yet, attachment research has, for most part, tended to focus on simple effects, for example through examination of concurrent or longitudinal associations between variations in attachment quality and developmental outcomes. When other variables have been included, it has often been as controls, for example to show that associations are not due to temperamental differences. However, just as the prevalence of the attachment patterns varies depending on factors such as socioeconomic status, with contextual variables thought to affect caregiver sensitivity, the association between attachment quality and developmental outcomes varies in strength depending on contextual and individual factors.

First, children typically have more than one caregiver and may have qualitatively different attachment relationships with different caregivers. As such, being secure with one caregiver may buffer against the risk from being insecure with another. Though relatively few studies to date have examined this issue, Boldt et al. (2014) found that attachment security with fathers in toddlerhood moderated the link between attachment security with mothers in toddlerhood and later behavior problems in school age. More specifically, children having low security scores with both mother and father showed the highest levels of behavior problems.

Second, other child characteristics, such as temperamental dispositions, may interact with attachment security in relation to subsequent development. As reviewed by Vaughn et al. (2008), research on interactions between these two domains, particularly in relation to interpersonal outcomes, started as late as during the 1990s. However, multiple findings now indicate that interactions between these two domains may be important, so that high temperamental reactivity together with insecure attachment increases the risk of maladjustment (Vaughn et al. 2008).

Third, contextual factors should be taken into account as moderators. As reviewed by DeKlyen and Greenberg (2008), multiple studies have found that attachment insecurity constitutes but one of many factors influencing further development, and associations between attachment insecurity and behavior problems may magnify substantially given the presence of contextual risk factors such as family adversity and additional unfavorable aspects of parenting. As such, insecure attachment may convey relatively little risk for a child who grows up with the presence of buffering factors such as a stable two-parent home, a sufficient and functioning social network, good access to peers, and access to good day-care.

Conclusion

Attachment theory has become a highly influential theory in psychology. Variations in attachment quality and organization have, in line with Bowlby's hypothesis, been robustly linked to broad measures of social adaptation and is linked to distinct aspects of social competence. However, we hasten to add that children's development is determined by so much more than attachment quality and therefore caution against simplified reasoning.

First, the amount of variation in developmental outcomes explained by individual variations in attachment quality is typically small, and particularly so in low-risk contexts. Second, and relatedly, associations between individual variations in attachment and developmental outcomes are moderated by contextual and individual factors. Attachment quality must therefore be seen in interaction with other aspects of development which magnify or buffer against risk, rather than as deterministically associated with subsequent development. Third, it is still unclear whether the various patterns of attachment are specifically linked to particular developmental outcomes, or if attachment quality (e.g., security/insecurity, organization/disorganization) constitutes a general protective vs. vulnerability factor. Fourth, most research conducted thus far has not accounted

for effects of other aspects of parenting, which may covary with caregiver sensitivity and child attachment and independently constitute predictors of the pertinent developmental outcomes. As such, it is still unclear to what extent attachment quality per se contributes to children's development beyond these aspects of caregiving. Fifth, several sets of mediators have been proposed, and it is at present unclear whether any of those are superior to the others, if effects of attachment are mediated by a number of different factors, or whether different mediators are implicated in relation to different developmental outcomes.

Although a challenging task, intensified examination of these issues represents important avenues for future attachment research in order to clarify the role of attachment quality in relation to children's development. Research following Bowlby has supported his general hypothesis that attachment quality is important for children's development, but there are still many unanswered questions.

Egg Ejection

► Egg Rejection

Egg Mimicry

William E. Feeney

School of Biological Sciences, University of Queensland, Brisbane, QLD, Australia

Synonyms

Cheating; Deception; Manipulation

Definitions

An evolved resemblance of host eggs by the eggs of avian brood parasites, resulting from Darwinian natural selection.

Introduction

The interactions between avian brood parasites, such as cuckoos or cowbirds, and their hosts have emerged as model systems to study coevolutionary processes under natural conditions. Instead of building a nest and tending their offspring, brood parasites lay their eggs in the nests of other birds and abandon the care of their young to the host. Adult parasites tend to remove or damage host eggs when depositing their own and parasite chicks generally eliminate the rest of the host's brood after hatching. Consequently, hosts evolve defences against brood parasites, which select counteradaptations in parasites, further counteradaptations in hosts, and so on. While evidence of reciprocal adaptations and counteradaptations in hosts and brood parasites are evident at all stages of the host's nesting cycle (Feeney et al. 2014b), the exquisite mimicry of host eggs by the eggs of some brood parasites comprise among the most charismatic and iconic examples of deception in the animal kingdom.

Egg Mimicry in Avian Brood Parasites

Mimicry as an adaptation to increase the likelihood of successful parasitism has evolved numerous times in the avian brood parasites (Feeney et al. 2014b). Best studied in the Eurasian common cuckoo (*Cuculus canorus*), it is most notably recognized as a counteradaptation to host discrimination (Brooke and Davies 1988). Preference for and coevolution with different hosts species can result maternally inherited host-specific egg phenotypes (Fossøy et al. 2016) that mimic those of their respective host species (i.e., host-specific egg “genres” or “races”; Gibbs et al. 2000), allowing for host specialization without speciation. Correspondingly, studies have empirically demonstrated the link between the degree of color (Stoddard and Stevens 2011) and pattern (Stoddard and Stevens 2010) matching and host discrimination across common cuckoo lineages and host species, when accounting for the host's visual perspective.

Outside of the common cuckoo and its hosts, studies have shed insights into other agents of

selection for egg mimicry by brood parasites, other kinds of mimicry resulting from brood parasite–host coevolution, and the amount of time it can take for these phenotypes to evolve under natural conditions. For example, in the dark nests of their crevice-nesting hosts, African greater honeyguides (*Indicator indicator*) produce eggs that mimic the size and shape of those of their hosts. However, rather than mimicry being a product of coevolution with their hosts, egg mimicry in this system is a product of selection imposed by competing honeyguides, which destroy nonmimetic eggs in order to maximize the likelihood of their own young surviving (Spottiswoode 2013).

In Australia, numerous small songbirds build dimly lit dome-shaped nests and produce white eggs with varying degrees of speckling. Rather than producing an egg that closely resembles that produced by any particular host, the Horsfield's bronze-cuckoo (*Chalcites basalis*) appears to have circumvented the defences of multiple host species, as well as the need to diverge into host-specific races, by producing an egg that generally resembles those of its multiple hosts (also known as “compromised,” “generalist,” or “jack-of-all-trades” mimicry; Feeney et al. 2014a).

Finally, the interactions between the African cuckoo finch (*Anomalospiza imberbis*) and its tawny-flanked prinia (*Prinia subflava*) host provides an elegant example of coevolution between the eggs of a brood parasite and its host, as well as unique insights into the timespan over which these kinds of evolutionary changes can occur. Unlike the common cuckoo, in which female-lineages are host-specific, selection imposed on the prinia eggs by cuckoo finches has selected numerous egg-races in prinias, which allows to more easily identify and reject cuckoo finch eggs that do not closely match their own. However, cuckoo finches have responded by evolving eggs that resemble those of the different prinia lineages (Spottiswoode and Stevens 2010). Further, Spottiswoode and Stevens (2012) used an egg collection that spans over 40 years to track the coevolution of egg phenotypes in prinias and cuckoo finches. They demonstrated that the pressure imposed on hosts by brood parasites can

select new phenotypes (i.e., egg colors) within this time period and that parasite egg phenotypes closely track those of their hosts.

Conclusion

Brood parasites commonly evolve egg mimicry in response to pressures imposed on them by either their hosts, or by other parasites competing for access to hosts. Selection imposed on brood parasites can select for host or host-race specific egg phenotypes, providing a clear and elegant example of naturally occurring coevolution.

Egg Rejection

William E. Feeney

School of Biological Sciences, University of Queensland, Brisbane, QLD, Australia

Synonyms

[Egg ejection](#); [Nest abandonment](#)

Definitions

A well-studied defense against avian brood parasitism in which a host “rejects” a brood parasite’s egg – either through physical ejection, burying the egg in the nest lining, or abandoning the nest.

Introduction

The interactions between avian brood parasites, such as cuckoos or cowbirds, and their hosts have emerged as model systems to study coevolutionary processes under natural conditions. Instead of

building a nest and tending their offspring, brood parasites lay their eggs in the nests of other birds and abandon the care of their young to the host. Adult parasites tend to remove or damage host eggs when depositing their own and parasite chicks generally eliminate the rest of the host's brood after hatching. Consequently, hosts evolve defenses against brood parasites, which select counteradaptations in parasites, further counteradaptations in hosts, and so on. While evidence of reciprocal adaptations and counteradaptations in hosts and brood parasites are evident at all stages of the host's nesting cycle (Feeney et al. 2014), rejection of foreign eggs by hosts is a well-studied defense that acts as a catalyst for subsequent coevolution between these species.

Egg Rejection as a Defence Against Brood Parasitism

Despite hosts employing an array of defense to prevent brood parasites laying eggs in their nests, it often occurs, which select adaptations in hosts that aim to minimize the cost of parasitism. Of these various adaptations (reviewed in: Feeney et al. 2014), rejection of foreign eggs often emerges as a key defense.

Iconic field experiments demonstrated that egg rejection behaviors are widespread, but not ubiquitous, among hosts of brood parasites (Brooke and Davies 1988; Rothstein 1975). Rejection of foreign eggs selects egg mimicry by parasites (Brooke and Davies 1988), which makes discrimination more difficult and increases the likelihood of hosts mistakenly rejecting its own egg. Hosts can decrease the likelihood of parasites laying eggs that match their own with individually identifiable "egg signatures" (i.e., female or race-specific egg phenotypes; Stoddard et al. 2014). Additionally, they can counter-egg mimicry with cognitive mechanisms that increases the likelihood of them accurately identifying and rejecting the correct egg (or eggs) in their nest (Stevens et al. 2013) and weigh the decision to reject an egg against their

perceived risk of parasitism (Thorogood and Davies 2016). Unlike other defensive adaptations, such as recognizing and responding to adult parasites near the nest, egg rejection behaviors appear to quickly become conserved after evolving, and can persist for at least hundreds of years after the pressure imposed by parasites has been removed (Lahti 2006).

Counteradaptations by brood parasites, or external ecological pressures, can generally explain why some species do not reject foreign eggs. For example, in the United States, brood parasitic brown-headed cowbirds (*Molothrus ater*) employ "mafia tactics" to ensure that hosts do not reject their eggs and increase the likelihood of successful parasitism. Unlike many parasitic cuckoos, cowbird nestlings do not always eliminate the host's entire brood, which allows for a circumstance where cowbirds monitor parasitized nests and repeatedly destroy the nests of egg rejecters until they succumb and accept the compromised, but not entirely diminished, reproductive output associated with hosting a cowbird nestling (Hoover and Robinson 2007). Similarly, despite Jacobin cuckoo (*Clamator jacobinus*) eggs being large and conspicuous in cape bulbul (*Pycnonotus capensis*) nests in sub-Saharan Africa, the combined effects of them being difficult to effectively eject with high external predation and the relatively low likelihood of the parasite's egg hatching in sync with the host's own eggs makes acceptance of the parasite's egg optimal in this species (Krüger 2011).

Conclusion

Egg rejection represents the best-studied counteradaptation that hosts employ to minimize the cost of brood parasitism. Research into the interactions across diverse parasite–host pairs highlights how ecological circumstances, available information, and the particular characteristics of the involved species shape this unique behavior.

Ego-Centered Kin Terminology

Sam Passmore

University of Bristol, Bristol, UK

Synonyms

[Kin system](#); [Kin terms](#); [Kin term system](#); [Kin terminology](#); [Kin vocabulary](#)

Definition

Ego-centered kin terminologies are when kinship terms are organized relative to the self, also known as ego. For example, if an individual says “(my) brother” that relationship is reckoned with respect to them, and the referent will not be the same as the listener’s brother (unless the ego and listener are siblings).

Alternatively, ego-centered kin terminologies show the genealogical relationships between individuals and are used as a visualization tool for representing kinship terminologies within languages, or within families/clans.

In Regard to Kinship Terms

The bilateral kinship network formed as the result of procreation is often used as the basis for kinship organization, and hence encourages the use of ego-centered kinship organization. That is, when a couple has a child, it creates a unique kinship network for that child, connecting both the father’s and mother’s family lineages. Societies impose cultural ideas on how an individual should behave toward various kin, e.g., who should be respected, and which kin have (or do not have) sexual taboos. Kinship terminologies provide a template of kinship categories that reflect these ideas, which can be applied to any individuals’ kin. However, there are suggestions that the

ego-focused basis of kinship studies imposes a European ethnocentric approach to kinship terminology and the understanding of societies' kinship organization (Schneider 1984).

The alternative to an ego-centered kinship organization is *sociocentric* organization, where individuals are organized based on a social category, as opposed to individual relationships (Dousset 2011). Here a group of individuals will all be referred to with the same term, based on their affiliation to a kin-based social category. These categories are often defined through lineage patterns, and are sometimes described as “skin” relationships, rather than kin (McConvell et al. 2018).

A second example of when kinship terms are not egocentric can be seen in the use of triangular kinship terms, commonly found throughout Australia, but also seen in Brazil and Patagonia. This is where a specific kin term is used by a speaker who addresses someone with whom they have a connecting relative. For example, a son speaking to his mother about his uncle, who is also the mothers' brother would use a specific term. In Biniñ Kunwok, a language from the Australian Northern territories, this term is *na-djumu* (Garde 2013). The mother would use a different term for the reciprocal relationship between her, her son, and her brother, since this covers a different set of relatives. These kinship terms are unique in that they are semantically denser than the traditional dyadic kinship terms, by taking both the speaker's and addressee's perspective on kin into account.

As a Visualization Tool

Ego refers to the central person in the terminology, to whom all relationships are extended from (Parkin 1997; Stone 2014). The ego can be gendered or gender neutral depending on whether the kinship language is dependent on the sex of speaker or not. For example, in Tongan, the term *ta'okete* means elder same-sex sibling, making the labeling of the terminology dependent on the gender of ego. English is an example of when ego is gender neutral. Typically, consanguineal (or blood) relatives are indicated by a single line, and parallel

lines indicate affinal relatives (or relatives by marriage). Men are often indicated by triangles and women by circles. However, this is not a universal custom and readers should take note of the author's legend or notes.

Emergence of Deontic Reasoning

Denise D. Cummins
Department of Psychology/Department of
Philosophy, University of Illinois, Champaign,
IL, USA

Synonyms

[Practical reasoning](#); [Social reasoning](#)

Definition

Reasoning about what one may, ought, or must not do in a given set of circumstances.

Introduction

Deontic reasoning is reasoning about what one *may*, *must*, or *must not* do in a given set of circumstances. Virtually all of our social institutions presuppose a capacity to understand and reason about what is *permitted*, *obligated*, *prohibited*, or *advised*. Failure to reason effectively about deontic concepts can have disastrous consequences, including social rejection, punishment, and even incarceration.

Deontic reference emerges quite early in children’s speech, appearing in children’s justifications of their behavior as early as 24 months of age.

Toddlers use terms such as *must* and *may* to talk about obligation and permission (e.g., “*You must stay*”), while epistemic uses of the same terms (e.g., “*It must be raining*”) do not reliably emerge until the 4th or 5th year of life.

Deontic reasoning is closely related to the concepts of *social norms* and *social contracts*. Social norms differ from social contracts in much the same way as laws differ from

Denise D. Cummins has retired.

contracts; norms (like laws) are prescriptive rules established by authority that dictate what is permitted or obligated under specified conditions, whereas contracts are agreements entered into freely by agents who promise a conditionalized exchange of benefits. Violating a norm means engaging in proscribed behavior, and there need not be any direct or immediate benefit to the agents controlled by the norm (other than avoiding punishment). In fact, many systems of social norms are enacted and enforced precisely to benefit some members of society over others. A violation of a social contract, on the other hand, is simply failure to reciprocate a benefit received that was given conditionally on reciprocation.

Emergence of Social Norm Reasoning

Beginning around 3 years of age, young children do not just follow social norms, they actively enforce them on others, even in situations in which they are not directly involved. They do not need to be explicitly instructed about the rules by an authority; they simply need to see an adult engage in it. For example, 3-year-olds will actively correct and admonish a puppet that interacts with an object in a way that is different from the way that an adult previously interacted with it, and they will use deontic/normative language to do so (e.g., “You have to do it this way”) (Schmidt and Tomasello 2012). Cummins (1996a) found that children as young as 3 years of age perform as well as adults when asked to monitor compliance with a norm. Children were shown toy mice, some of which squeaked when squeezed. Children were told either “*The Queen Mouse says all the squeaky mice are in the house*” (epistemic) or “*The Queen Mouse says all the squeaky mice must stay in the house*” (deontic). They then had to choose whether to squeeze toy mice that were inside or outside of a toy house to “*make sure no one is disobeying the rule*” (deontic) or “*find out if she’s wrong*” (epistemic). Across two experiments, two thirds of 3-year-olds correctly chose to squeeze the mice that were outside the house in the deontic case, but only one third chose to do so in the epistemic (truth-testing) case. Similarly,

Harris and Nuñez (1996) showed children cards that illustrated compliance with or violation of social rules such as “When Julie rides a bicycle, Julie wears a helmet.” Children were required to find the picture that showed either that the sentence was wrong (epistemic) or that Julie was doing something wrong (deontic). Preschool children were found to perform nearly optimally on the deontic versions of the task but frequently made errors on the epistemic versions of the task.

Emergence of Social Contract Reasoning

Within the first year of life, infants engage in reciprocal turn-taking behavior with caregivers, and by at least the third year of life, children are selective in their distribution of altruistic acts, preferring to aid those who have aided them in the past. Children as young as 4 years of age reason effectively about reciprocal exchange, correctly identifying instances of contract compliance as well as instances of cheating (Harris et al. 2001).

Explanations of Early Emergence

Differences in learning opportunities. One explanation for the ease and speed with which children induce deontic reasoning strategies is the frequency and urgency with which deontic reasoning situations present themselves during early childhood. In other words, there is ample opportunity to induce a schema for reasoning about deontic situations given their ubiquity. Yet children are exposed to instances of lying (epistemic violations) as frequently as instances of misbehavior (prescriptive violations).

Despite this, we induce no efficient schemas for testing truth. Children and adults agree on what constitutes a violation of a social rule, but considerable disagreement exists among theorists concerning how the truth of statements should be tested. Moreover, both adults and children frequently employ deficient strategies (e.g., confirmation bias) when asked to test the truth of statements (see Cummins 1996b for a review).

Differences in the complexity of meta-representations and satisfaction conditions.

Some researchers have argued that epistemic reference emerges later than deontic reference because the former is more demanding of meta-representational cognitive resources. But epistemic sentences do not require more complex operators than deontic sentences to capture their logical forms. Deontic sentences usually include modals to express permission (“You *may* do that”) and obligation (“You *must* do that”). Epistemic sentences use the same modals to express possibility (“You *may* be right”) or necessity (“You *must* be the one who did it”). Epistemic sentences also need not make use of modals (“It is raining”) and hence are syntactically simpler than deontic sentences.

The same can be said about task complexity. Deontic and epistemic versions of reasoning tasks require children to detect discrepancies between a mental representation of what should be (e.g., “Squeaky mice must stay/are in the house”) and the actual situation (e.g., “Squeaky mice are not in the house”). In both cases, the state of affairs described and the actual state of affairs must be compared in order to assess whether their satisfaction conditions have been met.

Despite this, epistemic tasks appear to impose greater cognitive load than deontic tasks. Van Lier et al. (2013) found that reasoning about deontic content does not depend on cognitive capacity or age and is unaffected when cognitive resources are burdened by performing a concomitant secondary task. In contrast, performance on a non-deontic version of the same task was found to depend on available cognitive capacity. This suggests that it is something about our cognitive architecture that makes it easier for us to understand and process deontic tasks.

Evolutionary explanations. Evolutionary accounts explain early emergence in deontic reasoning by arguing that this type of reasoning was a target of selective pressure. The first researchers to offer an evolution-based explanation were Cosmides and Tooby (1989), who proposed **Social Contract Theory**. They argued that performance improves only when people interpret the materials as social contracts with reciprocal benefit structures. An offer to engage in social

exchange can be expressed by a rule of the form: If Benefit [to Party X, from Party Y] then Benefit [to Party Y, from Party X]. Subjects encountering such a rule should perceive that individuals who have accepted a benefit without returning a benefit are cheating. Cosmides and Tooby argued that algorithms for reasoning about social exchange evolved in protohumans during the Pleistocene, making them species-specific cognitive architecture.

Cummins and Cummins (1999) offered an alternative evolutionary explanation which they call the **Learning Bias and Canalization View**. Learning bias refers to attentional biases for social stimuli (e.g., the preference of newborns to look at faces as opposed to equally complex stimuli). Canalization refers to the degree to which the development of a trait is robust across normal environmental variations. According to this view, all infants are “primed” to rapidly acquire social rules due to an attentional bias toward social stimuli, but *which* rules are acquired depends on the norms characterizing their particular social groups (canalization).

They further argue that this kind of cognition is not unique to humans but instead reflects cognitive functions that were shaped over evolutionary time by the exigencies of living in social groups. Numerous primatologists have noted that primates are endowed with cognitive abilities that are especially well suited to tracking social information. They are able to recognize individuals, identify kin, keep track of past interactions with group members, discriminate between cooperators and defectors in reciprocal interactions, and form alliances based on reciprocal obligations (such as grooming and food sharing) (Silk 2007). These characteristics of primate cognition have measurable fitness consequences, that is, measurable impact on the frequency of an individual’s genes in the gene pool via differential reproductive success. It is difficult to defend the position that humans were exempt from this evolutionary pressure.

These accounts are bolstered by neuroimaging of reasoning pathways. For example, in a study conducted by Canessa et al. (2005), the effect of content on brain activation was investigated with functional magnetic resonance imaging (fMRI)

while people solved the truth-testing and deontic versions of the Wason selection task. They found that both tasks activated a left-hemispheric fronto-parietal network, which is consistent with a number of studies that report left hemisphere involvement in deductive reasoning. But deontic content was also found to recruit activity in right-hemisphere frontal and parietal regions while truth-testing content did not. This selective recruitment of right hemisphere areas is consistent with other studies showing a major role of the right hemisphere in the processing of social content.

Conclusion

Thriving in a complex social environment depends crucially on deontic reasoning. Humans and other social animals appear to be biologically prepared to rapidly learn what is permitted and what is forbidden in a social group, and readily detect transgressions of social norms and contracts. They also readily form alliances based on reciprocal obligations, and monitor transactional imbalances. These basic social cognitive functions are, in a very real sense, what the social brain evolved to do.

Theoretical reasoning

Definition

Reasoning to determine what is true.

Denise D. Cummins was retired.

Introduction

Reasoning about what is true is referred to in philosophy as *theoretical* reasoning or *discursive* reasoning. It is also referred to as *epistemic* reasoning in developmental psychology, and *indicative* reasoning in psychological research that studies the way people reason about indicative statements. Indicative statements are simple assertions such as “*I am tall*,” as opposed to statements that describe subjunctives such as “*If I were taller*” or include modals such as “*It must be raining*.”

Research has shown that development of the capacity to reason about truth is quite protracted compared to other types of reasoning. For example, toddlers use modals such as “*may*” to express permission (“*You may do that*”) and “*must*” to express obligation (“*You must do that*”). Epistemic sentences use the same modals to express possibility (“*You may be right*”) or necessity (“*You must be the one who did it*”), but these types of utterances do not reliably emerge in children’s language until the 4th or 5th year of life (Ozturk and Papafragou 2015). It is not until this age that children also begin to reliably pass versions of theory of mind tasks that tap children’s understanding of epistemic states such as true and false beliefs, and tasks that depend heavily on frontal lobe executive functions, such as switching rules by which objects must be sorted (Henning et al. 2011). Second-order mental state understanding (e.g., *Peter knows that Sally thinks it is raining*) does not emerge until about 6 years of age, and it undergoes steady development well into adolescence (Sullivan et al. 1994).

While reasoning about true and false beliefs in the social realm undergoes development, reasoning about truth and falsity on nonsocial tasks remains uniformly low throughout the lifespan. For example, 3 year olds perform poorly on reasoning tasks that require them to test the truth of indicative conditional rules. Cummins (1996a) showed 3- and 4-year-old children toy mice, some of which squeaked when squeezed. Children were told either “*The Queen Mouse says all the squeaky mice are in the house*” (epistemic) or “*The Queen Mouse says all the squeaky mice*

must stay in the house” (deontic). They then had to choose whether to squeeze toy mice that were inside or outside of a toy house to “*make sure no one is disobeying the rule*” (deontic) or “*find out if she’s wrong*” (epistemic). Across two experiments, two-thirds of 3-year-olds correctly chose to squeeze the mice that were outside the house in the deontic case, but only one-third chose to do so in the epistemic (truth-testing) case. Four-year-olds correctly chose the outside mice over 80 % of the time in the deontic condition, but performance on the truth-testing version remained unchanged at 33 %. Adults show the same magnitude differences on adult versions of deontic and truth-testing selection tasks (Cummins 1996b).

Similarly, Harris and Nuñez (1996) showed children cards that illustrated compliance with or violation of social rules such as “*When Julie rides a bicycle, Julie wears a helmet*.” Children were required to find the picture that showed either that the sentence was wrong (epistemic) or that Julie was doing something wrong (deontic). Preschool children were found to perform nearly optimally on the deontic versions of the task but frequently made errors on the epistemic versions of the task.

Theoretical Explanations

Differences in learning opportunities. One explanation for deficient epistemic reasoning strategies relative to social reasoning strategies is that there is ample opportunity to induce schemas for reasoning about deontic situations given their ubiquity in the child’s everyday experiences. Yet children are exposed to instances of lying (epistemic violations) as frequently as instances of misbehavior (prescriptive violations).

Despite this, we induce no efficient schemas for testing truth. Children and adults agree on what constitutes a violation of a social rule, but considerable disagreement exists among theorists concerning how the truth of statements should be tested. Moreover, both adults and children frequently employ deficient strategies (e.g., confirmation bias) when asked to test the truth of statements (see Cummins 1996b for a review). Moreover, normative theories of hypothesis-testing are

relatively recent developments in the history of science (see Cummins 2012, chapter 7). The importance of adopting a falsification strategy was articulated as recently as the mid-twentieth century.

Differences in the complexity of meta-representations and satisfaction conditions. Some researchers have argued that epistemic reasoning emerges later because it is more demanding of metarepresentational cognitive resources. But indicative sentences do not make use of modals, and hence are syntactically simpler than deontic sentences.

The same can be said about task complexity. Deontic and epistemic versions of reasoning tasks require children to detect discrepancies between a mental representation of what should be (e.g., “*Squeaky mice must stay/are in the house*”) and the actual situation (e.g., “*Squeaky mice are not in the house*”). In both cases, the state of affairs described and the actual state of affairs must be compared in order to assess whether their satisfaction conditions have been met.

Evolutionary Explanation

Psychological investigations have repeatedly shown that adults and children perform better when evaluating compliance than when evaluating truth, and this difference has been replicated in dozens of experiments using a variety of experimental tasks over the course of 30 years (Cummins 1996b). Adults and children typically find the truth-testing version much more difficult than the deontic version of the task, even when the tasks require identical responses and even though they do not differ in representational or strategic complexity.

It should also be noted that while there is agreement among logicians concerning normative treatments of deontic conditionals, no consensus has been reached on how to capture the truth conditions of indicative conditionals (Edgington 2014). This suggests that it is something about our cognitive architecture that makes it easier for us to understand and process deontic tasks, a conjecture that is supported by two lines of evidence.

First, epistemic tasks appear to impose greater cognitive load than deontic tasks. Van Lier et al. (2013) found that performance on a nondeontic task declined when reasoners were burdened by performing a concomitant secondary task while deontic versions of the same task were unaffected.

Second, deductive reasoning typically activates a left-hemispheric frontoparietal network. Canessa et al. (2005) found that both deontic and truth-testing reasoning tasks activated this network. But deontic content also recruited activity in right hemisphere frontal and parietal regions, areas that play a major role in the processing of social content. The recruitment of this additional network apparently facilitates understanding and reasoning about social content.

Conclusion

Reasoning about truth depends on executive functions that are applied broadly across domains and develop slowly over the course of brain maturation and development. In contrast, deontic reasoning appears to benefit from specialized cognitive architecture that develops quite quickly in childhood to facilitate cognizing the social world.

University of Massachusetts Amherst,
Amherst, MA, USA

Synonyms

Cognitive development; Dominance hierarchies; Social status

Definition

The development of the ability to use cues to dominance, such as physical power, social power, or access to resources, to reason and make inferences about species-specific social hierarchies.

Introduction

Social hierarchies, defined here as organizational structures in which certain individuals or groups have greater social power and/or access to resources than others, are ubiquitous across cultures and species (Cheney and Seyfarth 2007). These hierarchies shape many aspects of life, from one's desirability as a social partner or mate, to overall health and well-being (Marmot and Sapolsky 2014). Social hierarchies serve to reduce the need for physical aggression, maintain group stability, and enable predictability in social environments; by knowing each individual's position in the hierarchy, one can predict the likely outcomes of interactions with group members and behave accordingly.

Given the ubiquity and importance of social hierarchies, it is not surprising that species from fish (Grosenick et al. 2007) to nonhuman primates (Bergman et al. 2003) can reason about hierarchies. For example, Hamadryas baboons expect dominance relations to be stable, and can infer – based on vocalizations alone – when unexpected dominance interactions occur (e.g., when a subordinate individual gives a threat-grunt – signaling dominance – to a more dominant individual: Bergman et al. 2003). Although social hierarchies are present in many species, most research in nonhuman species has only examined the *consequences* of hierarchies, such as investigating how an individual's rank in a hierarchy shapes physiological functioning, mortality rate, or access to food or mates (see Cheney and Seyfarth 2007; Marmot and Sapolsky 2014). The question of *how* individuals develop the ability to reason about hierarchies has largely been asked only in humans. Therefore, this entry reviews the literature on the emergence of reasoning about hierarchies in humans, shown to be capable of this type of social reasoning before reaching their first birthday.

Hierarchies: Simply Complicated

Dominance hierarchies are simultaneously simple and complicated. They are simple because the

defining trait of a hierarchy is an asymmetric relationship. In other words, hierarchies arise when two individuals are in a zero-sum situation where only one can achieve the desired outcome. For example, if two children both want to play with a toy, but there is only one toy, then a hierarchy is formed between those two children, and the child who gets to play with the toy is the dominant individual and the child who does not get the toy is the subordinate.

Hierarchies are also complicated. First, although each individual dominance relation is established between two individuals, hierarchies are often constructed at the group level and therefore include more than two individuals. Thus, to learn the larger, group-level hierarchy, group members must keep track of dyadic (i.e., one-to-one) dominance relations and then construct the group-level hierarchy from each of these dyadic relationships. Importantly, individuals can construct the group-level hierarchy by observing some (but not all) of the dyadic dominance relations, inferring unseen dyadic relations through transitive inference. In this context, transitive inference is the ability to derive an unknown dominance relation between two actors based on knowledge of the dominance relations each of those actors has with a shared, third actor. In other words, after observing A prevail in an asymmetric interaction with B, and B prevail over C, transitive inference would lead one to expect A to prevail over C, even without seeing any prior interactions between A and C. Second, hierarchies can be constructed both within a single group (*intragroup* hierarchy, as described above) as well as between groups (*intergroup* hierarchy). Therefore, in addition to constructing intragroup hierarchies based on interactions between two individuals, individuals must also develop the ability to see groups as cohesive units and construct intergroup hierarchies based on the interactions of two groups. Third, asymmetries can be based on a wide variety of factors, from access to resources, to social power, to influence over others. Thus, children must learn how to detect cues to asymmetric dominance relations using each type of factor; for example, being able to represent concepts such as “more” versus “less”

(for asymmetric resource-based relations). Fourth, and relatedly, the factor that a given hierarchy prioritizes is likely to vary across different contexts. For example, while playing in their neighborhood, children might form a hierarchy on the basis of the number of toys each kid has (prioritizing access to resources). In contrast, when at school, children might form a hierarchy on the basis of power or prestige (prioritizing influence over others), putting the school principal at the top of the hierarchy, teachers in the middle, and students at the bottom (for a detailed review of reasoning about dimensions of status hierarchies in adults, see Mattan et al. 2017). Despite the sometimes complicated nature of hierarchies, humans – even from infancy – are remarkably good at identifying cues to dominance that signal hierarchies.

Learning Cues to Dominance

In fact, humans seem predisposed to organize the world in a hierarchical fashion from an early age. Infants as young as 15-months-old learn and remember dyadic dominance relationships and use these to construct linear dominance hierarchies (e.g., where $A > B > C > D$, and so on: Mascaro and Csibra 2014). When presented with two actors that infants have seen interact separately with a third actor, but not interact with each other, 10-month-olds use principles of transitive inference to predict the outcome of this novel interaction (Gazes et al. 2015). A predisposition toward hierarchical organization continues into adulthood. Adults can better perceive, remember, learn (and even prefer) asymmetric relationships (in which one actor is dominant to the other) than relationships in which both actors are equal in status (Zitek and Tiedens 2012). Finally, although it has yet to be examined in infants, 5-year-old children have spatial representations of hierarchy, representing dominance in a vertical space where the powerful are higher than the weak (Lu et al. 2017).

In infancy, one particularly salient cue to dominance is size (reviewed in Pun et al. 2017). Ten- (but not eight-) month-old infants expect

bigger individuals to be dominant to smaller individuals (Thomsen et al. 2011). When shown a video where two blocks – one larger and one smaller – vie for the same goal, infants expect the larger block to prevail, exhibiting surprise when the larger block bows down (acts subordinate) to a smaller block, but not when the smaller block acts subordinate to the larger block. By 12 months of age, infants expect these dominance relations to be stable across different contexts; when shown a video where one actor (A) wins a physical contest over another actor (B) in one context (i.e., gaining access to a contested space), infants then expect actor A to prevail over B in a new context (Mascaro and Csibra 2012). However, when infants are shown A interacting with a new actor (not-B), the infants do not expect A to prevail in this new interaction context, suggesting that infants view dominance relations as specific to a given pair of individuals (in this case, specific to A and B, and not generalizable to A and not-B). Even younger infants are sensitive to cues of dominance, using numerical group size to infer dominance. Employing a similar paradigm of contested interactions as described above (in Mascaro and Csibra 2012; Thomsen et al. 2011), Pun et al. (2016) found that 6-month-olds expect groups with fewer members to be subordinate (and defer) to groups with a greater number of members.

Infants and children are capable of using even more subtle cues, such as facial physiognomy (i.e., facial structure or features), to detect dominance. Faces with more masculine and mature features (e.g., rated as looking aggressive and older by adults) are perceived as more dominant by adults, as well as by children as young as 3-years-old (Cogsdill et al. 2014). Even infants are sensitive to these types of cues; 13-month-olds differentiate between scenarios where puppets with more masculine faces prevail from scenarios in which puppets with less masculine faces do (Hartstein et al. *under review*).

Young children can use more dynamic cues to infer dominance relations as well, although this ability has only been documented later in development (i.e., after infancy). By 3-years-old, children can use a variety of cues to detect dominance,

including physical supremacy (e.g., who prevails in a physical fight), number of resources (e.g., who has more toys), and age (e.g., who is older: Charafeddine et al. 2015). Five-year-olds (but not 3- or 4-year-olds) can infer which actor is dominant based on nonverbal cues such as body posture (e.g., standing with shoulders back vs. hunched over, head up making eye contact vs. head down with no eye contact, etc.: Brey and Shutts 2015). Providing multiple cues to dominance appears to simplify the task; when given verbal input in addition to seeing nonverbal cues (i.e., when the dominant individual gave instructions and the subordinate asked for instructions), then even 3-year-olds are able to identify who is in charge (Brey and Shutts 2015). In contrast, a separate research study conducted on 4- to 9-year-olds found that children were incapable of understanding that the one who gives instructions is dominant to the one who accepts them before the age of 7 (Gülgöz and Gelman 2016). Some of the variation across studies in the age at which children have the ability to detect and infer dominance from various behavioral cues is likely to be due to methodological differences. Thus, more research studying how and when children come to use different cues to construct social hierarchies will help clarify the developmental trajectory of this aspect of cognitive development. In sum, when presented with a variety of cues to dominance in dyadic interactions, children are remarkably accurate at inferring who is dominant and who is subordinate, and even infants are capable of using dyadic interactions to construct group-level hierarchies (Mascaro and Csibra 2014).

Applying Dominance Hierarchies to Real-World Social Groups

Understanding how children come to organize the people and social groups around them into social hierarchies is important. Children, and adults, often prefer people and groups at the top of the hierarchy (Bigler and Liben 2007), perhaps due to the fact that high-status individuals have preferential access to resources as well as social capital and thus are likely to be beneficial social or

coalitional partners (Cheney and Seyfarth 2007). This preference for high-status groups is evident even among individuals who belong to stereotypically low-status groups (e.g., a pro-White bias among Black children in the USA, see Raabe and Beelmann 2011). Much of the work on children's ability to reason about hierarchies and to apply hierarchical organization to the social groups around them has focused on two social categories that are important in much of western culture – race and gender.

In cultures where race and socioeconomic status co-vary, children begin to view racial categories in a hierarchical fashion during early childhood, and children make inferences about status using a variety of cues to dominance. When given information about occupations that differ in prestige, 6-year-old children in the USA believe Black people are more likely than White people to have low-status occupations, and expect novel occupations to be lower status when they are described as held by Black people (Bigler et al. 2003). When presented with differences in resource holding (by being shown possessions that vary in quality or quantity), preschool-aged children expect White people to have higher quality and quantity of resources than Black people in both the USA (Elenbaas and Killen 2016; Mandalaywala et al. [under review](#); Shutts et al. 2016) and South Africa (Shutts et al. 2011).

Resource holding might be a useful cue to dominance for racial categories, given the types of input children are likely to be exposed to (through media, in their daily interactions, etc.). However, information about resources might be less informative when considering how status hierarchies map onto gender categories. For instance, although the gender pay gap is well discussed among adults, wealth differences between men and women might not be salient to children, particularly those growing up in heterosexual two-parent households. Indeed, previous work found that 3- to 9-year-old children in South Africa did not use gender to predict who had nicer possessions, although they did use race in this manner (Olson et al. 2012). In contrast, when presented with prestige-based cues to dominance, such as occupation, 5- and 6-year-

olds organize gender categories in a hierarchical fashion, rating stereotypically male-biased professions (e.g., scientist) as higher status than stereotypically female-biased professions (e.g., teacher: Liben et al. 2001). When given information about symmetry in social power (i.e., differential ability to make decisions for others), children as young as 3.5-years-old say that males are higher in the social hierarchy than females (Mandalaywala et al. [under review](#)). Less work has examined how young children reason about hierarchies outside the context of race or gender, for example, in the context of the caste system in India (but see Dunham et al. (2014) for evidence that children as young as 9-years-old are aware of the relationship between caste and wealth, rating Brahmins as wealthy and Dalits as poor).

Applying Hierarchies to the Self

Although children are aware of the dominant stereotypes about status, at least as they are applied to culturally-relevant social groups, they do not readily apply these stereotypes to themselves. This suggests a disconnect between knowledge of stereotypes and internalization of stereotype content. Although children between the ages of 3.5- and 7-years-old display awareness of culturally relevant stereotypes about status hierarchies, these same children do not apply societal stereotypes about status hierarchies to themselves. At these ages, even children who belong to groups that are stereotyped as lower-status (e.g., female or African-American children) perceive their own status to be high (Mandalaywala et al. [under review](#)). In other words, children's subjective social status (e.g., their perception of their place in a social hierarchy) does not shift in accordance with their objective social status (e.g., their status based on group-membership is a stereotypically higher or lower status social group). This is an important point, as subjective social status is a strong predictor of health and well-being. Although socioeconomic status (SES, often determined through a combination of educational attainment, occupational prestige, and income) is obviously important for determining

access to resources and opportunities, among adults, subjective status can differ from SES. Importantly, people who feel lower in the hierarchy than their SES would imply (i.e., having lower subjective status) have more health problems and are likely to die at a younger age than their SES-matched peers who do not feel low in the hierarchy (Singh-Manoux et al. 2005). Whereas young children seem relatively immune to the potentially pernicious consequences of subjective status, by 10-years-old, children's subjective status assessments begin to match family SES (Mistry et al. 2015). Better understanding exactly when and why children begin to view their subjective status as lower, and when they start to view themselves as members of group-based social hierarchies more generally, will help us understand the development of reasoning about hierarchies.

Conclusion

From an early age, humans are able to use a variety of cues to infer dominance and can use these cues to construct social hierarchies. Although this work sheds light on the types of dominance cues individuals use to determine social standing, it is unclear how infants and children determine what cues to dominance are the most relevant and informative in their environment and to the particular hierarchy in question. A cue such as being physically larger in body size is used to signal and infer dominance relations across a broad swath of non-human species and thus is likely to have ancient evolutionary roots. Therefore, we might expect among humans that larger body size is cross-culturally understood as signaling dominance and that individuals infer dominance based on larger body size from early in development. However, other cues, especially those based on culturally-specific concepts of prestige, are likely to be culturally dependent (e.g., being a priest may be prestigious in Italy, a predominantly Catholic country, but not in Saudi Arabia, a predominantly Muslim country). To best understand the role of cultural input on the development and consequences of children's reasoning about hierarchies, cross-cultural work looking directly at the types of

input about status hierarchies that children are exposed to will be necessary. Finally, although very little work has examined the development of reasoning about dominance relations in non-humans, comparative research would shed light on the cognitive adaptations underpinning the evolution of humans' rather remarkable (but not unique) abilities to structure complex societies into stable, informative hierarchies.

Emma Darwin

Vicki K. Bentley-Condit
Department of Anthropology, Grinnell College,
Grinnell, IA, USA

Introduction

Emma Darwin is best known not so much for who she was or what she did but for being the wife of Charles Darwin. However, “wife of Charles” does not begin to address her importance or her life.

She was intelligent, well-read, and had strong opinions which she was not afraid to state. She was an outgoing woman with many friends and family members who enjoyed the quiet of country life. She was a devoted wife and mother who also pursued her own interests. In short, she was as complex as any modern woman and deserving of a closer examination of her life.

Early Life

Emma Darwin (*née*: Wedgwood) was born on May 2, 1808, and was the youngest child and fourth daughter of Josiah Wedgwood II. From a young age, she was known for her high spirits and general lack of tidiness. Emma grew up in a very liberal household. The Wedgwoods were a family of readers. They encouraged liberal thinking, education, an intellectual lifestyle, free speech, and respect for all people. They were also very active in their support for the abolition of slavery. Emma knew French, German, and Italian. She also rode, danced, was an archer, and was gifted at playing the piano. Reportedly, she received some lessons from both Moscheles and Chopin (although the latter remains unverified). Emma developed a love of politics early and followed political news closely throughout her life. Much of what we know about Emma is through copies kept by herself and her family members of her frequent correspondence and through a journal she kept from the age of 16 until her death (Litchfield 1915a, 1915b; Loy and Loy 2010).

Marriage to Charles

As a Wedgwood and part of the extended and intertwined Darwin-Wedgwood family, Charles and Emma knew each other for most of their lives. Charles proposed and Emma accepted on November 11, 1838. There followed many letters between members of the two families expressing their delight at the pairing. Charles worried that he was not good enough and did not deserve a wife such as Emma. He also worried that she would find life with him far too quiet and dull after growing up in a lively household. He stated in a letter to her that he hoped to prove himself worthy

of her and, perhaps foretelling the future, that he needed her to take care of him. In a letter to her aunt, Emma remarked that one of Charles' traits that made her happy was his lack of fastidiousness; however, she was unhappy that he did not enjoy attending plays. They married on January 29, 1839 (Litchfield 1915b).

Emma's primary concerns regarding getting married were leaving her sister, Elizabeth, to be the sole care-taker of their mother and father who both had failing health when they had been sharing those duties and Charles' dwindling or lackluster Christianity. The latter, to Emma, meant they could not be together in the afterlife. All indicators are that Charles and Emma fell deeply in love with one another – if not before the wedding then certainly afterwards – and she obviously married him despite her worries (Litchfield 1915a, 1915b; Loy and Loy 2010).

Josiah Wedgwood and Robert Darwin, Charles' father, both contributed to the new couple's financial well-being on the announcement of their betrothal. Emma brought into the marriage £5000 in investments and a £400 annual allowance while Charles received a £10,000 investment with £600 per year expected in dividends. Combined, in today's terms, this equates to a net worth of \$1.25 million with an annual income of approximately \$83,000. They were quite well-off when first married and continued to accumulate wealth and property over the years via investment, inheritance, and earnings from Charles' publications. By today's standards, they were multimillionaires by the time they were 50 years old (Loy and Loy 2010).

Middle Life

By the middle of 1844, Emma was in her mid-30s and Charles had finished a 230-page draft of his "species theory." He wrote Emma detailed instructions on what to do with the draft, who to have edit it, what publishers to approach, etc. in case he died before doing anything with it himself. Despite their differences when it came to religion, he completely trusted Emma to fulfill his wishes regarding the document. Additionally, he had her act as his first editor – reading, commenting upon, and correcting the manuscript wherever she

encountered grammatical issues, unsupported assumptions, or questionable conclusions. By all accounts, she was a meticulous taskmaster. Charles then put the manuscript aside. Emma's role here was important as this was one of the first steps leading to the publication of Charles' evolutionary work (Loy and Loy 2010).

Emma was also very social – far more so than Charles – and placed great stock in lively conversation. When not pregnant, she would make frequent trips to London to socialize, attend concerts, and see plays. Sometimes Charles would go with her, other times he would not. Though social, Emma also tended to be very matter-of-fact in her approach to life. When Charles received the Royal Medal for Natural Science in November of 1853 – a high honor – Emma's only comment in her diary was that he had gone to London (Loy and Loy 2010).

Emma's final pregnancy of ten, in 1856, occurred when she was 48 years old. She had suffered from pregnancy sickness through them all. For the last, she took "blue pills," which contained mercury, to help with the sickness. For her last few pregnancies, she used chloroform during the birthing process. Her last child, Charles Waring Darwin, may have had Down's Syndrome or may have had some level of retardation due to mercury poisoning in utero from the pills (Loy and Loy 2010).

Emma's nursemaid skills were called upon throughout her life. Not only did she take care of Charles through his many bouts of recurring and debilitating illness but also most of her children were ill to very ill at various points. The Darwins lost their first daughter, Annie, when she was only 10 years old to what may have been tuberculosis. Some of the children contracted but survived scarlet fever while her last baby, Charles Waring, died of that disease at only 18 months of age. Others, such as Henrietta, were sent off to hydropathists for "water treatments" (the same as those Charles endured) for months at a time in an attempt to address their ailments. It has been suggested that there may have been a "cult of ill health" at Down House fostered by an overly solicitous mother (Emma) that, at some level, encouraged invalids. However, it is also very true that there was serious illness after serious illness (e.g., diphtheria, scarlet fever, tuberculosis, measles, typhus/typhoid fever)

within the family and all members seem to have suffered from perennial dental problems requiring extractions (Loy and Loy 2010).

Late Life

In 1859, Emma again worked with Charles on what had become *The Origin of Species* by helping him to read and correct the proofs from the publisher. Although she did not agree with the ideas presented therein and continued to worry about Charles' soul, Emma was willing to accept what she considered the "bad" with the "good" of being with Charles Darwin in their 20th year of marriage. She did, in fact, rejoice with him over the positive reviews and commiserate over the negative ones. In the following years, Emma would also function as Charles' personal secretary, helping him to deal with the high volume of correspondence he both sent and received (Loy and Loy 2010).

Despite their very different opinions regarding religion early in their marriage, Emma's views changed significantly over the 43 years that they were married. Not long before Charles' death on April 19, 1882, Emma remarked to one of her children that her opinions, like those of Charles, differed significantly from those of her son's very religious fiancée. Emma was too ill to attend Charles' funeral and did not view his gravesite at Westminster Abbey until almost one year later. Following Charles' death, Emma split her time between Down House and a residence in Cambridge with her daughter, Bessy. Two of her sons, Horace and Frank, built houses on either side of the Cambridge house, thus creating a Darwin compound there (Loy and Loy 2010).

By her 77th year, Emma's strength and stamina were on the decline and she spent more and more time in her "bath chair" – an early version of a wheelchair. Her hearing was also diminishing. She was, however, still a voracious reader and spent much time following the political scene. That same year, 1885, her son Frank was working on *The Life and Letters of Charles Darwin*, which included the short autobiography Charles had written as a memento for the family. Emma worked with Frank to edit Charles' comments

on religion, removing passages she thought might be offensive to others or that she felt not worthy of his memory. It was not until 1958 that an unabridged version of the autobiography was published by Charles' and Emma's granddaughter (Loy and Loy 2010).

Conclusion

Emma Darwin does not really have a "claim to fame." Charles was the famous member of the family. However, she formed the core of their family, kept the household functioning, suffered though many births and deaths, entertained the minions who flocked to Charles like moths to a lantern, and facilitated Charles' ability to write and publish. Without her, it is doubtful that Charles could have accomplished all that he did. She was, in short, the steady foundation upon which Charles built his opus.

Definition

Emotional closeness is used to measure the strength of a relationship. Humans tend to feel emotionally closer to genetically close kin compared to more distant relatives or non-kin. Emotional closeness is also high between spouses and affinal kin, who share a reproductive interest in mutual offspring.

Individuals feel more compassion for and provide more help to emotionally close others. Among close kin, however, emotional closeness explains only part of the willingness to help.

Introduction

Emotional closeness is a kind of magic wand for scholars of sociality. Close dyadic bonds are the foundation for primate cooperation, and a seemingly trivial question – “how close do you feel to ‘x’?” – taps deep also into human behavior.

Charles Darwin (1871, p. 308) was the first to link the “all important emotion of sympathy” to social behavior and family relations. Emotional closeness has since been confirmed as a crucial factor in assessing relationship strength, alongside other factors such as contact frequency, geographical proximity, and the types of activities engaged in together (Dunbar and Shultz 2010). Today, emotional closeness is commonly used in surveys and experiments to assess the quality of a dyadic social bond at a particular moment. Emotional closeness can be assessed verbally or visually through the inclusion of other in self (IOS) test (Aron et al. 1992).

Feeling emotionally close is associated with trust, commitment, empathy and compassion, and a willingness to help and support the concerned individual (e.g., Korchmaros and Kenny 2001). Its function may be to enhance the smoothness of interactions between individuals. Since processing all past interactions in each social encounter would be cognitively encumbering and slow, mammals including humans appear to rely on a feeling of “bondedness” to guide their actions. Thus feeling close may provide a psychological shortcut to whether a particular individual should be helped or trusted.

Closeness and Kinship

Kinship is one of the most robust predictors of emotional closeness. Bondedness between family members extends beyond the functional tasks of mating and parenting: it characterizes human sociality across the life course (Emlen 1995). Emotional closeness is also typically higher towards members from an individual’s own group, between individuals who have a shared history of coresidence, reciprocal support or interaction, and among females.

Close genetic relatives are known to preferentially associate with each other across the life course. This behavior is partly explained by emotional closeness among kin. Based on inclusive fitness theory, emotional closeness can be expected to emerge among individuals who are closely genetically related and of high

reproductive value to each other (Hughes 1988). Indeed, empirical studies have consistently found emotional closeness to correlate with degrees of genetic relatedness in different societies. For instance, aunts and uncles who are monozygotic twins are socially closer to their nieces and nephews, to whom they are 50% related, compared to aunts and uncles who are dizygotic twins and on average 25% related to their nieces and nephews (Segal et al. 2007). Korchmaros and Kenny (2001) found that emotional closeness accounted for around 30% of the effect that genetic relatedness had on helping behavior.

Emotional closeness cannot, however, fully account for altruistic behavior towards close kin. Nepotistic tendencies are to be expected among kin also irrespective of emotional closeness. Close relatives are helped even when they are not particularly liked, and the relationship includes strain and conflicts. This effect has been called the “kinship premium” (Curry et al. 2013). Among non-kin, by contrast, emotional closeness is more strongly correlated with altruistic helping, as well as more easily taxed by arguments or loss of trust (Stewart-Williams 2008).

Closeness and Reproductive Interest

Two additions should be made to the general and positive association between genetic relatedness and emotional closeness. First, emotional closeness among kin can coexist with or be superseded by kin competition. For many years after weaning, human infants are exceptionally dependent on the resources provided by others. Since the flow of these resources is usually from the older generation to the younger, resource competition is likely to be especially severe between members of the same generation, such as siblings and cousins (Hughes 1988). This can explain why the closest friends typically score higher on emotional closeness in Western societies than siblings do (Stewart-Williams 2008).

Second, it is not so much genetic relatedness in itself, as investment in shared and dependent offspring that characterizes the social dynamics of cooperative breeders such as humans (Emlen

1995). Emotional closeness among adults can therefore be predicted to be highest among individuals who cooperate to protect and rear shared descendants (Hughes 1988), for example, among the parents and grandparents of a child. This is the ultimate reason for why emotional closeness tends to be strong between spouses, who are usually not closely genetically related, and why having a child may strengthen the emotional bond between a couple and their parents-in-law (Danielsbacka et al. 2015).

Conclusion

Emotional closeness varies with gender and age, so that females experience it more, and it is more often directed towards subjects of higher reproductive value, who usually represent the younger generation.

As the saying “blood is thicker than water” denotes, the greater their genetic relatedness or shared reproductive interest in offspring, the closer individuals become. Thus genetically close relatives, as well as spouses and affines, tend to feel emotionally closer to each other than to non-kin. Their mutual sympathy can also stand more strain and conflicts than other relationships can. The tendency for higher emotional closeness among close kin can be reduced by kin competition. Emotional closeness does not fully account for altruism among close kin.

Emotional Disposition

Indrikis Krams
University of Tartu, Tartu, Estonia

Synonyms

[Character](#); [Nature](#); [Temper](#); [Temperament](#)

Definition

The tendency to have a particular type of affective experience, most often toward the type of experience the person has already had.

Introduction

Consciousness is considered to be the state of being aware of an external object (van Gulick 2004) or something within oneself (Farthing 1992). An emotion reflects the current state of consciousness and influences behavior (Schwarz 1990). Thus, an emotional disposition is an important part of the mechanism of consciousness as a persistent tendency to feel a specific kind of emotion in the presence of a certain object. Although the original states of emotion arise under certain general types of situation rather than specific individuals, living creatures, or things, they come to be associated with certain individuals or nonliving things while obtaining personal experience. After being formed this way, emotional dispositions manifest themselves in the form of actual emotion on specific occasions.

Importantly, the term “emotional disposition” is not the same as an “emotional mood.” While mood is an actual affect of consciousness, emotional disposition occurs even when either the mood or the emotion itself is not being felt. Therefore, such broadly used words as “like” and “love” generally suggest emotional dispositions rather than emotions currently felt. As pointed out by William McDougall (1932), “on the higher levels of mental life, where ideas and concepts play a prominent part, emotional dispositions are very complex, and are called Sentiments or Interests.”

Emotional Dispositions and Character Traits

Emotional dispositions are often compared with character traits, since some individuals may be more prone to experiencing certain emotions. Sensitive people can start feeling anger sooner when their personal boundaries are being violated than less sensitive individuals (Novaco 1986). Paul Ekman, an American psychologist who is a pioneer in the study of emotions and their relation to facial expressions, suggested to classify the following emotions as basic: anger, disgust, fear, happiness, sadness, surprise. He subsequently

added ten more basic emotions to his list: amusement, contempt, embarrassment, excitement, guilt, pride in achievement, relief, satisfaction, sensory pleasure, and shame (Ekman 1999). All of these emotions are linked to personality traits and are thus related to emotional dispositions.

Emotional Dispositions and Personality Characteristics

Personality research shows a link between dispositional positive and negative affect and the Big Five factors such as extraversion, conscientiousness, agreeableness, openness to experience, and neuroticism (McCrae and Costa 1991; Shiota et al. 2006). For example, extraversion is positively correlated with predicted frequency and intensity of felt positive emotion, as well as reactivity to positive feedback representing positive emotional predisposition (Bachorowski and Braaten 1994; Wilson and Gullone 1999). These results also suggest that relationships between dispositional positive emotionality and the Big Five personality variables are far more complex than previous research indicates, opening new horizons in future studies to fully understand the relationships between human personality and emotional dispositions.

Regulation of Altruism by Emotional Disposition

Robert Trivers, an American evolutionary biologist and sociobiologist, proposed the theory of reciprocal altruism – i.e., contingent cooperative investments between non-kin individuals that are based on the cooperative returns (Trivers 1971). He stated that certain emotional dispositions linked to social structures and cultural traditions are important in explaining the tendency to cooperate or cheat. Trivers suggested that people differ in the degree of tendencies and responses based on emotional dispositions. These dispositions are crucial for creating friendships/partnerships, and they affect human culture and the structure of societies. Robert Trivers proposed the following

emotional dispositions that are evolutionarily linked to reciprocal altruism in humans:

1. Friendship and emotions of liking and disliking. These emotional dispositions are important for an act of altruism to take place.
2. Moralistic aggression. This instrument is a part of the mechanism to protect an altruist against cheaters. The moralistic altruist functions to instruct/punish a cheater.
3. Gratitude and sympathy. Receiving gratitude can encourage altruistic responses by a receiver.
4. Guilt and reparative altruism. Guilt may prevent the defector from defecting/cheating again.
5. Subtle cheating. This type of cheating was used to explain the existence of adaptive sociopathy.
6. Trust and suspicion. Measures to control for cheating and subtle cheating.
7. Partnerships. Kind of altruism to create partnership and alliances.

Emotional Dispositions in Social and Political Life

Anger and fear as dominant aspects of modern political life are considered as emotional dispositions/emotional states often being exploited by domestic or international elites and mass media for political purposes (Lupia and Menning 2009; Hatemi et al. 2013). A considerable part of political science deals with the methods by which the public is manipulated through the activation and escalation of fear and anger (Brader 2005; Abramson et al. 2007). An interesting study by Skitka and colleagues (2004) demonstrated that in response to 9/11, individuals who were angry but not fearful supported expanding the war beyond Afghanistan, while fearful but not angry individuals supported deporting Arab Americans and first-generation immigrants out of the country. Importantly, a significant heterogeneity in fear disposition was found between individuals (Neale and Fulker 1984; Kolassa et al. 2008), which is partly due to genetic differences

(Olsson et al. 2005; Santos et al. 2010). This shows that dispositions such as fear are malleable but can be manipulated only to a certain extent. This is a significant finding in light of the role that genetic and other biological factors have on formation of political attitudes (Schreiber and Iacoboni 2012).

Conclusions

Emotional dispositions are important for understanding behavioral decisions that humans and other organisms make as individuals, groups, and societies. Some emotional dispositions and their evolution can be understood in terms of regulation of altruism. Emotional dispositions are linked to personality and thus are dependent on genetic and physiological factors. Multidisciplinary research is therefore of major importance in this field.

Emotional Jealousy

Christina Bentancourt and Joseph A. Camilleri
Westfield State University,
Westfield, MA, USA

Definition

An emotional state that occurs in response to a perceived or real threat to one's intimate relationship, specific to when a partner directs time and resources to another person.

Emotional Jealousy

Jealousy is defined as an emotional state that occurs in response to a perceived or real threat to a social relationship (Buss et al. 1992). When a perceived or real threat occurs, people respond in a way that counteracts the threat in order to protect the relationship, suggesting jealousy is an evolved adaptation (Buss et al. 1992; Buss and Haselton 2005). Jealousy in intimate relationships takes one of two forms: *sexual jealousy* and *emotional jealousy*. Sexual jealousy occurs in response to a partner's sexual involvement with another person (see ► [“Sexual Jealousy”](#)), whereas emotional jealousy occurs in response to emotional involvement with another person. Men and women both experience sexual and emotional jealousy, though data and theory suggests the sexes may differ on the degree to which they respond to either type.

Several studies have examined the underlying factors that lead to emotional jealousy within relationships. Traditionally, psychologists considered jealousy a pathology that manifests itself identically in both men and women. However, evolutionary-informed research has suggested that men are more likely to find sexual infidelity more distressing due to cuckoldry risk, (i.e., cuckoldry risk is the risk of unknowingly raising unrelated offspring; male sexual jealousy in response to cues to partner infidelity is hypothesized to have evolved in response to such a risk, Buss et al. 1992). whereas women are more likely to find emotional infidelity more distressing due to

Emotional Distress

► Girls Psychological Bullying

the potential loss of commitment and resources (Buss and Haselton 2005; Buss et al. 1992). This latter situation is particularly salient to women because a barrier to women's fitness is mate quality, which includes accessing their partner's resources to assist with raising and protecting offspring. Men who pursued long-term emotional relationships with other women posed reproductive costs to their partner due to a loss in parental investment. These actions are not as costly to men because their reproductive success increases through mate number. Thus, it has been argued that women are more sensitive to emotional jealousy because it identifies a reproductively relevant threat and motivates them to minimize such a threat.

Consistent with this hypothesis, Buss et al. (1992) found that 60% of men reported greater distress over their partner's sexual infidelity whereas 83% of women reported greater distress over their partner's emotional infidelity. Use of alternative operational definitions also found converging evidence. For example, using Electrodermal Activity (EDA) to measure autonomic arousal, men showed a significant increase in EDA when imagining sexual infidelity compared to imagining emotional infidelity, and women showed a significant increase in EDA when imagining emotional infidelity.

Although many studies have replicated these sex differences in emotional jealousy, the magnitude of these differences varies across cultures (e.g., Buunk et al. 1996), and some have suggested the effect is not robust (Harris 2003). For example, some have been critical of using forced choice options (i.e., participants need to choose which of sexual and emotional infidelity is worse), finding that sex difference effects disappear when using continuous measures of emotional and sexual jealousy (DeSteno and Salovey 1996). There were, however, methodological issues with these studies (Sagarin 2005), and a follow-up meta-analysis using more appropriate methodology found evidence supporting sex differences on types of jealousy, even when using continuous measures (Sagarin et al. 2012).

Psychometric investigations of emotional jealousy require greater attention. There does not appear to be a clear method for independently assessing emotional jealousy. Most measures

consider other psychological responses to emotional infidelity, which may or may not be valid indicators of emotional jealousy, such as outrage, sadness, worry, among many others (see Sagarin et al. 2012). Specifically, Shackelford et al. (2000) identified 103 possible emotional responses to infidelity, and these items factored in 15 components: undesirable/insecure, hostile/vengeful, depressed, helpless/abandoned, happy, shocked, nauseated/repulsed, blameworthy, content/relieved, humiliated, sexually aroused, tired, homicidal/suicidal, anxious, and forgiving. Although Shackelford tested to see if these outcomes varied by sex and infidelity type, it is still not clear if some psychological responses are specific indicators of emotional jealousy or if they are outcomes from it. This literature would benefit from psychometric research on the validity of quantifying emotional jealousy by testing for its content validity and discriminant validity from sexual jealousy. Developing psychological assessments specific to quantifying variation in emotional jealousy will assist with further research on evaluating its causes, consequences, and function.

In the psychological literature, emotional jealousy varies in its operational definition because it can also refer to its affective response, which differs from cognitive jealousy and behavioral jealousy. A psychometric study found that items in a measure of jealousy fell into one of these three factors, and that emotional jealousy was positively associated with relationship love, whereas cognitive jealousy was negatively associated (Pfeiffer and Wong 1989). This literature has some inconsistent findings – although emotional jealousy is associated with relationship love, others found that it is negatively associated with happiness and relationship satisfaction (Pfeiffer and Wong 1989; Anderson et al. 1995). Further theoretical and empirical works on understanding emotional jealousy as an affective component are needed.

Emotional Solutions to Free Riding

Timothy Ketelaar
New Mexico State University, Las Cruces,
NM, USA

Synonyms

Emotions; Free rider

Definition

A free rider is an individual who benefits from accessing a public resource, but does not contribute toward the sustainability of that resource. The core logic of an emotional solution to the free rider problem centers on the idea that emotions can provide powerful incentives for an individual to cooperate in sustaining a public good as well as powerful incentives to punish those who fail to cooperate in sustaining a public good.

Introduction

The classic example of free riding is Hardin's (1968) *tragedy of the commons* in which the unregulated grazing of cattle on a parcel of common land leads to the eventual depletion of that resource through overuse. The role of emotions as solutions to the free rider problem can be illustrated by combining behavioral economics methodologies (e.g., modeling social interactions as bargaining games) with insights from evolutionary psychology (the idea of emotions as strategic decision-making devices).

The core logic of how emotions might solve the free rider problem centers on the idea that emotions can function as strategic commitment devices that compel individuals to pursue strategies that maximize long-term payoffs rather than pursuing strategies that promise spuriously attractive immediate rewards (see Nesse 2001; Ketelaar 2006 for reviews). The sentiment of gratitude, for example, can compel an individual to repay an act of kindness even when the cost of repayment exceeds the initial benefit bestowed upon the actor (Hirschleifer 1987). While costly acts of gratitude-inspired reciprocity may provide no immediate rewards, the benefits of such acts (e.g., stronger alliances, increased social capital) can be reaped in future social encounters. Similarly, the emotion of guilt can compel a person to redress a harm that they have inflicted upon another party, even when there is little chance of immediate retaliation from the offended party. As such, guilt functions to maximize the long-term benefits of immediately

redressing such harms (or signaling your willingness to do so) by repairing the damage done to a relationship with a potential long-term social interaction partner.

So, how can emotions such as anger or guilt function as commitment devices that solve the problem of free riding? One mechanism by which anger can function as commitment device is by serving as a guarantor of threats directed toward under-contributors in collective actions (see Hirshleifer 1987, 2001 for a more general discussion of emotions as guarantors of threats). The *ultimatum game* studied by behavioral economists, for example, provides a nice environment in which to study anger and social decision-making. The *ultimatum game* consists of a social bargaining game in which a communal resource is split between two parties. One party (the ultimatum-giver) proposes how the resource is to be divided, but the final decision regarding whether the resource is actually divided (in the manner proposed by the ultimatum-giver) lies in the hands of the recipient of the ultimatum. In one study of the ultimatum game, it was observed that feelings of anger (reported by the ultimatum recipient) were associated with rejections of unfair ultimatums (Pillutla and Murnighan 1996). Other studies have found that participants make greater concessions in negotiations when they believe that their negotiation partner is angry than when they believe that their partner is happy (Van Kleef et al. 2004). In another study that is more directly related to the free rider problem, one third of the participants in a repeated public goods game consistently punished group members who made deviant contributions. Of particular relevance to the role of emotions in solving the free rider problem, it was observed that these costly acts of punishment were directed toward low contributors and were linked to feelings of anger on the part of the punishers (Fehr and Gächter 2002).

Through a somewhat different psychological mechanism, guilt can also serve as a commitment device that solves the problem of free riding. Consistent with the notion that guilt provides a powerful incentive to cooperate when there is a

temptation to behave in a self-interested fashion, one study found that 57% of participants in a repeated ultimatum game reported feelings of guilt after proposing an unfair division of the money in the first round of play. More important, these feelings of guilt were predictive of increased cooperation in the second round. More specifically, 91% of the participants who felt guilty after proposing a selfish offer made a subsequently generous offer in the second round. By comparison, only 22% of the participants who felt no guilt after making a similarly unfair offer made a generous offer in the second round (Ketelaar and Au 2003). The link between feelings of guilt after engaging in self-interested behavior was also demonstrated in a study of the iterated prisoner's dilemma where increased cooperation was associated with feeling guilty after behaving non-cooperatively. This study found that individuals who felt guilty immediately after defecting across several rounds of the iterated prisoner's dilemma subsequently displayed 25% more cooperation compared with those who reported felt no such feelings of guilt after defecting (Ketelaar and Au 2003).

Conclusion

Emotions can “solve” the free rider problem by functioning as commitment devices that compel individuals to contribute to a public good and to punish those who fail to cooperate in sustaining a common resource. Certain emotions – such as guilt – can compel an individual to cooperate even when it is not in their immediate self-interest to do so, whereas other emotions – such as anger – can compel an individual to punish those who fail to cooperate in sustaining a public good (Ketelaar 2006).

Emotions

Eliza Bliss-Moreau
 Department of Psychology, California National
 Primate Research Center, University of
 California, Davis, CA, USA

Definition

Emotions are phenomena that emerge from more basic biological and psychological ingredients, which represent the relationship between the

function of a person's physiological systems, past experiences that the person has had, and the context in which the person is in the moment, to provide granular, context-specific information that organizes experience and can be used to guide action.

Introduction

An emotion is an emergent phenomenon that represents the relationship between the function of a person's physiological systems, past experiences that the person has had, and the context in which the person is in the moment to provide granular, context-specific information that can be used to guide action. Emotions – such as anger, happiness, sadness, and fear – emerge from more basic or fundamental biological processes within individual people, as well as basic or fundamental social processes created by groups of people. Neither the individual-level nor social group-level processes are specific to emotions, but rather those processes serve many functions, of which supporting the generation of emotions is one. That is to say, emotions are not circuits in the brain or body, nor do they arise from discrete dedicated biological circuits. Neither are emotions sociocultural programs or modules that are exclusively learned in, or exist solely as a result of, social contexts and experiences. Rather, human emotions arise from the interplay between complex biological systems which are embedded into human social systems.

Definitions of emotion as emergent phenomena arise from a variety of academic traditions including philosophy, anthropology, psychology, sociology, and neuroscience. As a result of this variability, different perspectives focus on different features which are necessary, sufficient, or simply important for the emergence of emotion. Even within a discipline, there is variable focus on particular ingredients. For example, psychological perspectives tend to focus on concepts, language, social relationships, and/or physiology (Barrett 2017b; Clore and Ortony 2013; Cunningham et al. 2013; Lindquist 2013; Mesquita and Boiger 2014; Russell 2003). However, psychological perspectives consistently

suggest that one component is thought to be critical for emotion to emerge – affect (sometimes called “core affect”; see Barrett and Bliss-Moreau 2009; Russell 2003) – in order to distinguish it from the generic term that refers to emotions, moods, feelings, etc.

Affect is discussed in the literature as both a biological phenomenon and a psychological phenomenon. Biologically, affect is a signal that results from an integration of interoceptive (processing of sensory signals arising from the body) and exteroceptive (processing of sensory signals arising from the environment) information and thus serves as a barometer representing an individual's place in the world (Barrett 2017b). In humans, this biological summary is available to be experienced as a psychological state. Psychologically, affect is a mental state characterized by some degree of valence (or hedonics, ranging from very good to very bad) and some degree of arousal or activation (ranging from very activated to very deactivated) (Barrett and Bliss-Moreau 2009; Russell 2003). In organisms that have the capacity to represent internal body states as “feeling,” affect is available to be felt consciously as feelings of pleasantness and unpleasantness or activation or deactivation. Importantly, human affect is not necessarily conscious (for a discussion of affect and consciousness, (Russell 2005)) – biological systems are always in action even if a person is unaware of his or her affective state. Major shifts in affective state (e.g., from neutral to positive or between degrees of positivity or negativity) capture attentional resources, allowing affect to be experienced consciously in some organisms. Directed top-down attention can also bring affect into conscious awareness – for example, asking oneself or being asked, how do you feel? Affective states provide the individual with global, agranular (or fairly nonspecific) information about its relationship to the world – e.g., this is bad for me, this is good for me – and produce course behavioral responses that subserve survival-related goals (e.g., move away, move toward). As a result, the presence of affect is sufficient to meet basic evolutionary challenges (e.g., survive long enough to reproduce) (Bliss-Moreau 2017; Bliss-Moreau et al. 2018).

Humans have long been the primary species for the study of affect – and in particular the conscious experience of affect – but humans are not the only species to have affect, although its nature and complexity may vary across the animal kingdom. For humans, physiological signals from the periphery generated by the autonomic nervous system are critical for affect (Barrett and Bliss-Moreau 2009; Craig 2011; Critchley and Nagai 2012) because they are interoceptive signals and they also mediate exteroceptive processes. Thus, we have hypothesized that nonhuman animals that share homologous (or nearly homologous) autonomic nervous systems with humans will have similarly structured and functioning affect (Barrett and Bliss-Moreau 2009; Bliss-Moreau 2017). Both functional and anatomical evidence from nonhuman primates speak to these homologies (e.g., Bliss-Moreau et al. 2013; Kawashima et al. 2005). Note that nonhuman animals need not have the capacity to consciously represent affect as feelings of pleasantness and unpleasantness or feelings of activation for the biological signals to impact behavior. In fact, the evolutionary roots of affect are thought to be present even in organisms that do not have nervous systems (e.g., chemosensing in bacteria which allows bacteria to move toward food sources and away from chemical environments that have the potential to kill them (Wolanin and Stock 2004).

While affect may provide the foundation for emotion and has been hypothesized to be a critical ingredient of emotion (i.e., without affect, there is no emotion), emotions cannot be reduced to affect (Bliss-Moreau 2018; Russell 2003). That is to say, happiness is not reducible to pleasantness, nor are fear, disgust, and anger reducible to intense physiologically activated unpleasantness. Fear, disgust, and anger – whose foundation is in the prototype case an intensely unpleasant negative aroused state – differ from each other in terms of the contexts in which they arise, the behaviors and thoughts associated with them, their functions, and even how they are experienced consciously.

Other components, processes, or “ingredients” must be added to affect in order for emotions to emerge. New approaches grounded in neuroscience and physiology adopt what is called

a predictive coding framework (Clark 2013) to understanding this emergence. The predictive coding framework specifies that animals' brains constantly generate models of the interplay between their internal (interoceptive) and external (exteroceptive) worlds in order to anticipate what resources are needed to take action at some point in the future (Barrett 2017b). In this view, the brain predicts what is coming next using information about the past, contextual information, and present sensory and physiological information, rather than only responding to present needs, thus engaging in allostasis (predictive or anticipatory regulation of physiology) rather than homeostasis (reactive regulation of physiology) (Barrett 2017b). Physiological processes associated with allostasis (via the autonomic nervous, endocrine, and immune systems) form the basis of interoception (Craig 2003). In humans (and likely in some other animals), all of this information is represented as mental states characterized by valence and arousal – affect.

Psychological approaches suggest that emotions come to be when what we know about emotion (conceptual knowledge) and a linguistic representation of that concept are linked to an affective state via attention resources (Lindquist 2017; Russell 2003). These approaches inherently recognize that the context in which emotions emerge contributes to their emergence, in part because conceptual knowledge includes contextual information. As a result, emotions are contextually bound, although the contextual information that helps to create an emotion need not be physically present at the time of the emotion – it can be represented as conceptual information and remembered or imagined. Some of these psychological approaches particularly emphasize the importance of social contexts for learning conceptual information and language (thus emphasizing the importance of social culture) and also creating a context in which emotions emerge (thus emphasizing the importance of interpersonal relationships).

Both biological and psychological approaches emphasize that emotions provide more granular information about the world and the individual's place in the world than does affect, allowing for more efficient navigation of both the physical and

social environments (for a similar argument, see Barrett 2017b). That is, when activated unpleasant affect which signals “this is very bad for me” is transformed into fear or anger or disgust, those discrete emotions include specific conceptual information from both the individual's culture (e.g., what contexts generate each emotion or when it is appropriate to have each emotion, words for the emotions) and the individual's past experience (e.g., early socialization about which emotions happen when, specific instances that have generated similar sensation before in similar contexts) that allow the generation of context-specific behavioral responses. As a result, discrete emotions are thought to have specific functions (e.g., Fischer and Manstead 2008).

Emotions sometimes, but not always, are associated with observable outputs. Outputs include vocalizations, facial behaviors, and other overt behaviors like body postures or movement, as well as physiological signals. It has long been believed by some scientists and the general public alike that these outputs map to emotions in a predictable discrete way – such that a particular facial behavior (e.g., a smile, crinkled eyes) either is generated as a result of a particular emotion or is part of that emotion (e.g., happiness), such that behaviors can be “read” to understand the emotion state of another person (hence the phrase “facial expression” which inherently assumes that the face expresses something specific) (e.g., Shariff and Tracy 2011). A robust literature, however, demonstrates that while people having emotions do sometimes generate behaviors or peripheral physiological changes, there is tremendous variance in the extent to which they generate outputs and the nature of those outputs and how those outputs are perceived (e.g., see these meta-analytic reviews on the face in emotion (Nelson and Russell 2013) and on physiological signals in emotion (Siegel et al. 2018). Context is such a powerful force that can even override the valenced (positive or negative) meaning of outputs (e.g., Kayyal et al. 2015). Context-dependent meaning of emotion-related outputs also appears to be evolutionarily old (for a review, see Bliss-Moreau and Moadab 2017). For example, rhesus monkeys (who share a lineage with humans some 25 million years ago) use their “silent bared

teeth display,” sometimes referred to as a “fear grimace,” in both agonistic and peaceful contexts, and the meaning of the signal (either “I submit to you just in this moment” or “I submit to you in perpetuity”) is dependent on the context (Beisner and McCowan 2014). Nevertheless, people’s strong intuitive sense that their perception of emotion in others results from “reading” emotion-related outputs most likely arises from the innate ability of healthy humans to make mental inferences about others (i.e., to ascribe mental states to other agents (Mitchell 2009)) rather than the generation of discrete emotion outputs themselves.

The evolutionary roots of human emotions are present in a variety of nonhuman animals and other living organisms, allowing for both comparative study and empirical study of the evolution of emotion (what we call *EvoEmo* (Bliss-Moreau 2017; Bliss-Moreau et al. 2018)). To date, thinking about *EvoEmo* has been dominated by the view that discrete human emotions (e.g., disgust, fear, happiness, etc.) evolved meet survival and reproductive goals (Tooby and Cosmides 2008). Basic survival and reproductive goals can be met by affect alone, however, as it provides an integrated representation of interoceptive and exteroceptive information at a given moment signaling what is good or bad for the individual (including representing information about intensity or magnitude). This view is consistent with the observation that many of the most successful species on the planet (e.g., bacteria, jellyfish, cockroaches) lack brains or brain structures that would be necessary for allowing emotions to emerge from affect and other ingredients. The hypothesis that affect is sufficient to meet survival and reproduction goals of seeking food and reproductive partners (good), and avoiding predators and poisons (bad), means that the evolution of affect can be studied in many different animals.

Conclusion

Considering affect as sufficient for basic survival raises new questions about how and why human emotions evolved emerged. One possibility is that human emotions supported, were supported by,

coincided with, or were required for the development of complex and large social groups that are characteristic of human societies – and violate many of the principles of optimum group size (for a discussion, see Bliss-Moreau 2017; for a similar argument, see Tomasello 2014). In this view, affect may have been sufficient to navigate finding calorie-rich food sources and avoiding poisonous foods, but affect was not sufficient for navigation of complex social interactions such as choosing a hunting partner who would consistently share his or her spoils without trying to steal your reproductive partner (Bliss-Moreau et al. 2018). Complicated social transactions benefited from more granular information about people and experiences – including the ability to integrate past information and make predictions about future situations – that could not be represented as associations and required abstraction. Thus, the emergence of emotions in evolutionary history may have coincided with the emergence of a particular type of conceptual information that was not bound by perception of statistical regularities in the physical environment into which interceptive information was integrated – abstract concepts about internal states (for discussions of abstract concepts and human evolution related to emotion, see Barrett 2017b; and in general (not specific to emotion) see Tomasello 2014).

Empathy in Rats

Molly McGuire
Oakland University, Rochester, MI, USA

Synonyms

[Emotional contagion](#); [Empathic concern](#); [Pro-social behavior](#)

Definition

Empathy is the ability to understand and mentally experience an event from another being's (human or nonhuman) frame of reference.

Introduction

In humans, prosocial behaviors (actions undertaken to benefit another person) require empathy. Empathy can be defined as an emotional reaction that occurs in response to the perception of need in another (Bartal et al. 2011). While there is clear evidence of empathy in primates (Yamamoto and Takimoto 2012), the evidence for empathy in other nonhuman species, such as rodents, is considered far more controversial.

Empathy can be thought of as existing on a continuous spectrum, with various subclasses

such as “emotional contagion” (in which an individual is affected by a conspecific emotional state). Langford et al. (2006) found evidence for emotional contagion in mice. They used the “writhing test,” in which either two mice were given injections of a solution to induced abdominal pain or one mouse was given saline while the other was given the painful injection. The mice were then placed into an apparatus where they could observe one another. They found that when both were given doses of the painful injection, the mice displayed significantly more behavioral indicators of pain compared to when only one mouse received the painful injection. These results imply that there was emotional communication of pain from one mouse to another resulting in a greater display of pain behaviors. Bartal et al. (2011) provided a new paradigm designed to test empathy in rodents through goal-directed behaviors. In their study, they investigated whether rats were motivated by empathic concern to release a conspecific from a physical restraint. Free rats were tested in an open arena which contained a restraining tube within which was a trapped cagemate. Researchers found that within approximately a week, the free rats had learned to consistently lift the door to the restrainer, releasing the trapped cagemate. Free rats were tested in three conditions: one in which the restrainer contained a trapped cagemate, one in which it contained a plush rat toy, and one in which the restrainer was empty. Bartal et al. (2011) found that the free rats were significantly more likely to open the door to the restrainer if it contained a trapped cagemate. To test whether the rats were only motivated to release the trapped cagemate as a way of attaining social contact, researchers ran the rats through another condition in which they prevented social contact after release of the trapped rat and they found that the free rats continued to release the trapped conspecific regardless. Lastly, researchers investigated the value of liberating a cagemate compared to the value of obtaining a preferred food reward. In this condition, the free rats were placed into an arena which contained two restrainers, one of which always contained a chocolate reward whereas the second

either contained a trapped cagemate or was empty. When the second restrainer was empty, the free rats opened the chocolate containing restrainer significantly faster. When the second restrainer contained a cagemate, there was no significant difference in the latencies to open the two restrainers. Furthermore, the free rats would often share the chocolate reward with their liberated cagemate even though the amount available was small enough for a single rat to consume in one sitting. These results provide strong evidence that rats will behave prosocially when faced with a familiar conspecific experiencing distress.

There is some controversy surrounding the interpretation of these results, however. Silberberg et al. (2014) suggested that the behavior of the rats in Bartal et al.'s (2011) study may have actually been due to a combination of neophobia and the pursuit of social contact. In their modified replication of Bartal et al.'s (2011) study, Silberberg et al. (2014) found that given enough time after release, trapped rats often return to the empty restrainer tube (which had been presumed to be aversive) in order to maintain a closer proximity to the free rat. Furthermore, when trained to touch the door of the restrainer to open it, the free rats continued to do so even when the restrainer did not contain a trapped cagemate. They further suggested that the trapped rats' behavior (immediately leaving the restrainer) in the earlier sessions may have been a neophobic reaction to restrainer itself and the act of the door opening. As time went on, the rats grew accustomed to the apparatus and the movement of the doors, explaining why the formerly trapped rats would then return to the restrainer in later sessions.

Conclusion

While there has been some support for both the empathy hypothesis and the social contact hypothesis in some experimental situations, neither hypothesis has been able to account for the behaviors of rats in these experiments across all

conditions. Vasconcelos et al. (2012) suggest that in order to infer empathic intent, researchers must be able to demonstrate that the apparently empathetic behavior of the animal is psychologically directed to reduce the distress of the trapped individual. One way to accomplish this task is to design a new paradigm which would ensure that the only outcome of the "empathic" behavior would be to reduce the stress of the trapped individual and not to cease the stress signals displayed by the trapped individual.

Employer Versus Employee

Gareth Crazee

Synonyms

Leadership vs. followership; Servant leadership;
Work relationship legitimation

Definition

The interface between people in relative positions of hierarchy and influence within the context of an employment relationship.

The construct of leadership likely has a long evolutionary lineage. It may have arisen, in part, as a psychological and structural solution to the challenges inherent in complex group coordination: conflict resolution, coalition formation, collective nomadism, and so forth. It could be argued that an individual's fitness would have been improved as a result of living in groups with effective leaders (Bastardo and Van Vugt 2018). If one were to imagine two largely identical groups of ancestral humans – both inhabiting the same physical environment and beholden to the same climatic and environmental parameters – with one governed by effective leadership and thus optimized decision-making and reduced group discord and the other not, then, all else equal, those fortunate enough to be part of the former will be better positioned to survive and reproduce. Thus, there is likely an ancient selective advantage for some variation on effective leadership (Van Vugt 2006).

However, leadership (and by logical extension followership) in this adaptive, ancestral sense – which was functionally bound up in immediate and salient survival objectives for vulnerable hunter-gatherers on the savannah of antiquity – is rather distinct from the kinds of social

relationships that characterize modern employer-employee relationships. In this context, survival-related goals are almost never a consideration (much less the major driving force) in these relationships, and the central interpersonal exchange in question is tied to the kinds of evolutionarily novel cultural artifacts that are typical of modern organizational life: productivity, remuneration, career progression, company values and objectives, and so on. As such, there is considerable scope for discordance between the adaptive faculties – both psychological and socio-structural – which gave rise to effective leadership in ancestral times, and the modern business contexts in which they are presently pressed into service (Van Vugt and Ronay 2014).

For one, the idea of formalized roles, job titles, and a granular delineation of responsibility which are characteristic of present day employee-employer relationships were simply not a factor in ancestral times. There were no “colleagues” as such, and no effective distinction to be made between “work life” and “home life.” Leaders were not recognized because of a codified position that could be understood as an abstraction and followers did not participate in their assigned tasks because an explicit contract formally rewarded them to do so. Again, all coordinated activity for which leaders took the reins was governed by the group's most immediately pressing survival demands (Li et al. 2018; Nicholson 2005).

While a return to a kind of “work life” where mere day-to-day survival is the group's principal aspiration would be neither practical nor preferable; there are varieties of employer-employee relationships which might better reflect and utilize our evolved capacities for leadership and followership, while also minimizing the potentially harmful impacts of evolutionary mismatch in this domain (Li et al. 2018). The idea of employees contributing in substantive, meaningful ways to the effective functioning of their organization might be one such solution. Employees tend to flourish in circumstances where they are actively involved in organizational life, and their personal

contributions to organizational outcomes are salient and apparent – a modern reimagining of the motivation to promote group survival. Smaller and flatter organizational structures that reduce hierarchies and anonymity within companies might be another solution: structuring organizations to more closely mimic the intimate and egalitarian social systems of ancestral humans, and harnessing the evolved psychological preferences of humans to work in smaller groups with people whose personalities and reputations one can keep track of (as opposed to the faceless impersonality of mega-corporations with thousands of employees, for example) (Van Vugt 2017).

Whatever potential solutions that organizations might operationalize in the service of structuring themselves along less evolutionarily discordant lines, the overarching message is that the employer-employee relationships of today's world are distinct from the leadership-follower relationships that have long been a part of the history of humanity. Recognizing this distinction, and where evolutionary mismatches might arise from it, ought to be of principal concern in any attempt to understand employer-employee relations through an evolutionary lens.

Definition

Men compete with other men for access to mating opportunities. Unemployed men who cannot appeal to women on the basis of their resource access may resort instead to violent competition. This provides an explanation for why young, unemployed men are the primary perpetrators of homicide.

Introduction

Acquiring the resources necessary for survival is a main focus of all living beings. Those with greater access to resources increase their ability to survive and reproduce. For males, resource access is essential both for their own survival, as well as their ability to attract mates. This leads to fierce competition among males. For humans, and most other animals, this competition can sometimes have a violent ending, with the main participants being those with the least to lose and the most to gain. This entry describes the violence and aggression resulting from this competition in unemployed men.

Evolutionary Background

Parental Investment Theory. Owing to sex differences in reproductive physiology, females have

a greater obligatory parental investment in offspring than do males (Trivers 1972). Among humans, successful reproduction requires that females produce the energy to sustain a 9-month gestation, as well as a long period of lactation following birth. The large investment of females limits the number of offspring they can have over their lifetime, leading them to choose their mates carefully, holding out for the highest quality suitor. This in turn has caused males to compete with one another for females and their parental investment (Trivers 1972). With males' parental investment being less than females, their fitness is limited only by their ability to secure mating opportunities with females. This incentivizes a short-term mating strategy that more strongly prioritizes quantity of mates over quality, allowing them to be much less selective in their mate choice relative to females.

Sexual Selection. The emphasis on short-term mating among males creates intense intrasexual competition among males for access to females. This competition may take the form of contests for direct sexual access to a female, as well as contests over access to resources that indirectly increase one's appeal to females. This competition produces selection pressure on males for traits that increase their likelihood of success. This provides an explanation for observed sex differences in height, physical strength, and violent and aggressive behavior. Males who opted out of this competition left behind fewer offspring than those who were successful, leading to the evolution of stronger and more aggressive males. Indeed, for males, it is either join the competition or be left with nothing.

Status and Reproductive Success. A key trait that predicts men's ability to successfully outcompete rivals for mating opportunities is their status. Men of high status typically have greater access to resources and are therefore preferred mates by women. Throughout history successful and high status men have deterred their rivals and increased their fitness. This is particularly true in polygamous societies where one man can have many wives, whereas other

men may have no wives at all. Betzig (1982) has documented the worldwide generality of absolute power and extreme polygamy. In Africa, harems have exceeded 1000 women, as they also have in India, China, and the Muslim world. As an extreme example, Mulay Ismail Ibn Sharif, the one-time emperor of Morocco, is estimated to have had 888 children (Daly and Wilson 1988). Similarly, estimates suggest that 0.5% of the world's population, and 8% of men in a large region of Asia, are descendants of Genghis Khan and his male-line relatives (Zerjal et al. 2003). In societies where one man has the means to do so, a large number of concubines are often kept (Daly and Wilson 1988). Indeed, men of high social rank have more wives, greater access to other men's wives, more children, and their children are more likely to survive than men of lower social status (Daly and Wilson 1988).

With their vast access to resources, women view high-status men as high-quality mates who are capable of providing for their offspring. Additionally, men may treat higher-status men with greater deference given their ability to control large shares of the group's resources. This has been the case in foraging, pastoral, horticultural, and state societies (Daly and Wilson 1988). The monopolization of mating opportunities by one or a few men creates fierce competition between men of lower social status, which may result in deadly violence as men with little to lose, and much to gain, struggle to gain access to mating opportunities.

Patterns of Violence

Wilson and Daly (1985) reported on a landmark study examining predictors of homicides in Detroit in 1972. The study revealed a pattern of violence supporting the theorizing that most homicides are motivated by competition for status among men.

Types of Homicide. Wilson and Daly (1985) discuss two types of crimes committed in 1972 Detroit, "crime specific homicides" and

“social conflict homicides.” As defined by Wilt (1974), crime specific homicides are cases where homicide was incidental to the omission of another crime (e.g., robbery) where the offender did not initially intend on killing the victim. Social conflict homicides are described as heat of the moment actions taken by the offender and not incidental to the omission of another crime. Social conflict homicides are a struggle for social resources that men deem valuable for their positive fitness consequences, including power, respect, and status. In contrast, crime specific homicides are a struggle for more tangible resources (e.g., money). The primary perpetrators of both types of violence are young men, particularly those who are unemployed.

Unemployed Men. The harsh reality of being a man of low social status is that mating opportunities are limited and the competition is more intense for you than it is for men of higher social ranking. Competition for females is the fiercest at the bottom of the scale where the male on track for total reproductive failure has nothing to lose and will therefore resort to violent tactics to improve his mating prospects (Daly and Wilson 1988). This may lead unemployed males to commit crimes, such as robbery, to gain the resources necessary to improve their fitness and deter rivals. Evidence of this comes from the research of Wilson and Daly (1985) who demonstrated that unemployed males in Detroit were more represented in crime-specific homicides (e.g., robbery 43%) than social conflict homicides (e.g., bar fights 39%). This may reflect a motivation of unemployed men to improve their social status through the acquisition of resources (Daly and Wilson 1988).

The prospect of reproductive failure may lead men to risk death in order to improve their reproductive success. This may explain why men who participate in risky criminal behavior or predatory violence have different time horizons, weighing the near future more heavily against the long term (Daly and Wilson 1988). This means that a man in a low status position will focus on what he has now (or does not have), instead of what he will have in the future. In comparison, men of higher status are more likely to make decisions

about how to act based on the future rewards or repercussions of those actions. The shorter time-horizons of unemployed men mean that the benefits gained from committing a crime (immediate increase in access to resources) outweigh the potential future consequences of that action. For instance, in Detroit in 1972, 43% of homicide victims and 41% of homicide offenders (across homicide types) were unemployed, as compared to 11% of all men in the city (Wilson and Daly 1985). The drive to improve fitness leads to risky decision-making and may cause men to participate in activities that put them at risk of ending up in prison, or dead.

Employed Men. In contrast to the unemployed, employed men have longer time horizons and focus more on how much they have to lose from engaging in risky, violent behavior. Engaging in violent behavior and/or criminal activity puts them at risk of losing the position that grants them high social status. Employed men are better served to compete for mating opportunities by conspicuously displaying their resource earning capacity to women, as opposed to putting that status in jeopardy by engaging in violent or criminal behavior.

Men with good jobs may deter rivals and attract mates as a function of their high status, making violence as a means to gain mating access unnecessary. A man with a good job or high social status may choose to walk away from a situation where his reputation is being tested and suffer no loss of respect from witnesses. Indeed, engaging in violent altercations may present more of a risk than walking away. In contrast, a man of low social status has only his reputation for toughness and therefore must respond to even minor insults in order to protect that reputation.

Conclusion

Unemployed men are more represented in crime specific homicides compared to social conflict homicides and are overrepresented in both types of crimes compared to the population of unemployed men in Detroit (Wilson and Daly 1985; Daly and Wilson 1988). Evolutionary theorizing predicts that men with low status and limited

reproductive opportunities will take drastic measures to increase their fitness. Men of low status are more likely to resort to violent crime in order to gain access to the resources necessary to attract mates, whereas men of high status have less to gain and more to lose by using violence as a way to improve their fitness.

Definition

Encoding can be defined as the neuronal activity which takes place in the brain during the acquisition or learning of a new task.

Introduction

Sleep is a type of behavior exhibited by numerous species on this planet, and although there is some variability in its individual characteristics across species, there are common patterns found in all mammals (Siegel 2009). Sleep is characterized by regularity in its occurrence around the circadian cycle. In diurnal animals such as humans, it

usually takes place during the dark whereas in nocturnal animals such as rats and mice, during the light phase of the 24-h period. The duration of sleep varies depending on the type of animal, with predators enjoying more hours of sleep compared to animals that are prey. Humans are placed in the middle of this continuum, with a duration of about 8 h of sleep per night. The use of electroencephalography in the study of sleep has allowed us to discover some of its intricate attributes, such as the different stages of sleep characterized by different patterns of electrical activity. Although numerous functions for sleep have been proposed over the years, the most prominent one seems to be its role in synaptic plasticity (Born et al. 2006). The discussion in this review will focus on the various processes that take place primarily during acquisition (encoding) and postencoding processes that promote learning and memory.

Sleep and Its Role in Encoding and Long-Term Memory

Sleep is characterized by different patterns of neuronal activity in the brain as measured by recordings of electrical activity using electroencephalography (EEG). The onset of sleep is characterized by increasing reduction of brain activity (stage 1) followed by further decrease in brain activity which is characterized by sleep spindles and K complexes (stage 2). This stage leads to further slowing of brain activity known as slow wave sleep (SWS) or deep sleep (stages 3–4) which is more evident at the beginning of the sleep period. A distinct phase of sleep, known as rapid eye movement (REM) or paradoxical sleep, is characterized by a high level of brain activity as well as rapid eye movements in combination with muscle atonia or paralysis. The REM episodes are rather short in the first part of the night but get increasingly longer as the night progresses. During this stage, most of our dreaming is thought to be taking place although dreaming may also occur during non-REM sleep (Stickgold 2005).

Although we have learned a lot about sleep in the past 50 years, there are still some important questions that are either unanswered or are

answered partly. The most intriguing question which is yet to be fully answered is in regards to its function. Numerous hypotheses have been proposed, such as conservation of energy, reduction of oxidative stress, and maintenance of optimal immune system function (Siegel 2009). Yet, the hypothesis which is gaining increasing support in the last few years is the role of sleep in learning and memory (Born et al. 2006).

Encoding can be defined as the neuronal activity which takes place in the brain during the acquisition or learning of a new task. Encoding itself is of course very important but even more critical is the neuronal activity which follows this initial encoding and allows for the establishment of new knowledge. Initially reported in rat hippocampal place cells, increased firing during exploration (wake) continued when the animals went to sleep. Thus, during sleep, the neurons replayed the previous experience perhaps in order to retain the information (Wilson and McNaughton 1994).

Studies done in humans were initially focusing on the overall role of sleep on learning and memory by applying a basic approach of allowing participants to sleep or not before taking a memory test, showing an advantage for the participants that were allowed to sleep before testing (Mednick et al. 2003). Both REM and SWS have been implicated in the enhancement of learning and memory. REM sleep has been more closely associated with the enhancement of nondeclarative tasks as well as the integration of new memories within existing semantic networks. SWS has been associated with the enhancement of declarative memories (Mednick et al. 2003; Born et al. 2006).

Following acquisition, a process known as consolidation must take place, in order for the newly acquired material to be kept for long-term use. The idea of consolidation has been proposed in 1900 by Müller and Pilzecker and was later supported by research evidence, demonstrating that the consolidation process involves the synthesis of new proteins and the formation of new synapses (see review: Born et al. 2006). Although the “seat” of memory creation is the hippocampus, especially for declarative memories, the memory traces themselves are not stored in the hippocampus itself. Following an initial phase of

strengthening the memory trace in the hippocampus, the memories are transferred to areas in the neocortex which were active during encoding, so that they can be available for future use. This process of redistributing information to the neocortex is known as systems consolidation, which not only allows for the distribution of memory traces across the cortex and thus the storage of long-term memories throughout the brain, but also for the emptying of the hippocampus so that new learning can take place (Born et al. 2006).

Sleep is thought to play an important role in this process, since accumulating evidence suggests that these important processes of consolidation mainly take place during sleep. For many years, the idea was that sleep strengthens the connections that are formed during learning; however, this may be half of the story. Sleep is not adaptive only because it helps strengthen the synapses formed during encoding but also because it helps to actively remove old memory traces from the hippocampus (Norimoto et al. 2018), in order to either transfer them to the neocortex for long-term storage (Khodagholy et al. 2017) or to eliminate them (Davis and Zhong 2017).

The idea of synaptic pruning during sleep was proposed by Tononi and Cirelli (2014). The synaptic homeostatic hypothesis (SHY), which they proposed, suggests that during wake there is increased firing due to encoding of new information; thus, synaptic pruning during sleep probably helps to reinstate the brain so that it can be able to function and learn more the next day. Indeed, recent studies in mice have shown that this may be an important function of sleep. During SWS, hippocampal neurons which were active during encoding continue to display increased firing whereas neurons which were previously active (remote traces) decrease their activity, most likely in a process which promotes the removal or weakening of remote memories which can be redistributed to other areas of the brain or to be erased altogether. This aspect of “weeding out” of memories may become possible by a characteristic pattern of neuronal activity during SWS, the sharp wave ripples (SWRs) which may transfer information from the hippocampus to the areas of the neocortex (Khodagholy et al. 2017).

Thus, during sleep, the brain is continuing to work in order to enhance prior learning, to help distribute learning that has been already established to other areas for long-term reference (long-term memories) as well as to remove information which is judged to be not needed. Although the intricate mechanisms by which the brain decides on how to select which neuron should be doing what have not been identified yet, it is a rather fascinating time as the secrets of the most basic mechanisms of learning and memory are beginning to become clearer. Sleep has an important role to play as it is the main platform during which this “tagging” of memories is taking place and during which the brain is constantly updating its “archives” in order to optimally reflect experience (Stickgold and Walker 2013).

Conclusion

It seems that an amazing story is unfolding when it comes to the role of sleep in learning and memory. During acquisition, the neurons implicated in learning enhance their firing in order to encode the information in a neural code, but the story does not end there. During sleep, the consolidation of memory takes place in the hippocampus via reactivation of the neurons involved, but as time passes these neurons will pass on their information to neurons in other cortical areas. In addition, memories which are deemed to be redundant are most likely erased in order for synapses to be available for new learning to take place. These complicated processes which have such an impact on our lives are taking place during this “offline” time, when we sleep. We may not feel it but when we sleep, our brains are orchestrating numerous processes which are crucial for our ability to learn and remember.

Definition

The process of converting natural resources into fuel for bodily function and maintenance.

Introduction

What unites all of life that has ever existed is what Charles Darwin called in *The Origin of Species* (1859), *The Struggle for Existence*. Every organism experiences various pressures against their ability to survive and/or reproduce. The most basic fuel for all organisms is nutrition, which may be in the form of a single nutrient or an entire animal. Mammals, especially humans,

require a large amount of energy in order to grow, survive, and reproduce. As diet and means of obtaining food evolved, early humans or *hominids* rose to the top of the food chain with their rapidly developing brain. Using an evolutionary psychological perspective, the higher functioning regions of the human brain can be traced back to its natural origins.

Biological Functions of Energy Consumption in Mammals

All contemporary mammals require food and water in order to live and maintain proper bodily function. At a cellular level, nutrients from plants or other animals are synthesized into a molecule called adenosine triphosphate or *ATP* by the cells' mitochondria (Magistretti et al. 2000). Processing food into energy, or *energy metabolism*, serves to regulate and maintain stable conditions in all bodily systems (Brandt 2008; Magistretti et al. 2000).

The fuel to synthesize nutrients or chemicals requires energy while the mammal, for example, maintains its body heat or locomotive power (Brandt 2008). The mammal's body is modulated by its central nervous system, the brain, which commonly requires some time in order to become completely functional. Today, *Homo sapiens* brains require almost three decades in order to completely develop (Del Giudice et al. 2015).

Evolution of Human Brain Energy Consumption

Early humans already had complex nervous systems, but the difference between modern and early hominid brains was mainly due to an increase in neuron circuitry rather than an increase in neurons (Hofman 2014). The catalysts of the brain's evolution remain under investigation, but Rachel Carmody and Richard Wrangham (2009) argue that cooking food is responsible for humans' world domination. Cooked food is generally more digestible than uncooked food; thus

its metabolization becomes more efficient. Potential pathogens within the food are significantly reduced, allowing humans to develop a more eclectic cuisine with a reduced risk of getting sick. The surplus of energy resources from cooked food is suggested to have enhanced the fitness of the human brain and body. Cooked food usually has a longer shelf life than raw food; henceforth, the task of feeding multiple humans became simpler (Carmody and Wrangham 2009).

Although cooking quickly became a human phenomenon, gathering was humans' main activity for food acquisition. Food from the vegetable kingdom was more abundant in the human diet than food from the animal kingdom. The more complex the human brain evolved, the higher its metabolic costs became. Although the general human *body* consumes most of the consumed energy, the human *brain* consumes a disproportionate amount of energy. The modern human or *Homo sapiens* brain accounts for about 2–3% of its body weight, yet it consumes about 500 calories per day, which is about a quarter of what the entire body needs on average (Harari 2015).

The brain's cerebral cortex distinguishes *Homo sapiens* from other hominid species. Its function and maintenance have become the predominant source of energy allocation within the brain. For neural networks to remain active and efficient, glucose and other resources are processed. When the human is active, all sensory functions simultaneously process information from the environment (Magistretti et al. 2000), which is not metabolically cheap.

A relatively recent discovery of the brain's energy expenditure is the *default mode network* (DMN). When the human brain is at rest or when it is not concentrating on a particular task, DMN activity *increases*. Current scientists who study the DMN observe that different regions of the brain become active when other regions become inactive. It is hypothesized that the purpose of the DMN is to nurture the brain and to organize newly processed information, which would account for the disproportionate amount of energy it consumes (Raichle 2015).

The Role of Cerebral Energy Metabolism on Evolutionary Psychological Research

Humans burn their calories 27% faster than what chimpanzees can burn. Other primates also do not have as high metabolic rates as humans (Gibbons 2016). In understanding what it means to be human as a recurrent theme of evolutionary psychological research, the nuances of the brain's functions are not ignored. For other animals, hibernation is hypothesized to allocate time for the organism to conserve its energy when its energy resources are scarce (Benington and Heller 1995). Although humans do not hibernate, numerous scientists believe that sleep is an evolutionary adaptation.

It is fairly common for humans to take short and long naps during the day. Both physical and mental exhaustion engenders the desire to rest the body and mind. From an evolutionary perspective, sleep can be as beneficial to the mind as it is to the body. Processing countless information each day depletes cognitive resources, which are suggested to revamp during sleep. Conserving cognitive resources is a valuable asset to human psychology. A complex brain that runs on a quarter of the body's consumed energy requires extensive maintenance, even when at rest or asleep (Del Giudice et al. 2015).

Evolutionary psychologists acknowledge that bodily services to the brain's overall fitness is as crucial as the body's overall fitness. The ultimate adaptation humans evolved is the ability to think, which may be argued as the most biologically expensive feature. The ability to reason, make pivotal decisions, communicate with others, simultaneously process information from the environment, and learn is founded upon the human's mental capacity. Although the occupations of hunting and gathering appear to be ancient, the *Homo sapiens* brain was engineered from ancestral pressures and conditions. Evolutionary psychologists strive to learn more about human psychology with the brain's natural functions and biological origins.

Conclusion

Every organism cannot survive without its energy resources. Food provides the organism with the most basic resources for all biological systems to operate long enough for it to reproduce. It is necessary for the mammalian brain to be equipped with higher cognitive functions in order to adapt to a diverse array of environments. Consuming cooked food is still debated to be the most unearthing treasure of the human brain. As long as the brain's functional origin remains a mystery, the science of evolutionary psychology will be relentless in its pursuit to understand human behavior.

ring may convey information about an individual's financial resources, commitment to the relationship, or preferences for certain features, such as for youth and nubility in women (Cronk and Dunham 2007). The custom of giving engagement rings provides opportunities for testing evolutionary hypotheses about mate preferences and mate guarding. Engagement rings may also signal other features, such as the aesthetic sensibilities of the couple or their beliefs about traditionalness, that are not easily related to evolutionary hypotheses (Dunham 2010).

Definition

An engagement ring is a ring given by a suitor around the time of a proposal of marriage. Although some engagement rings are family heirlooms, more often they are purchased either by the suitor alone or by both members of the betrothed couple. In the United States, an engagement ring is conventionally worn on the third finger of a woman's left hand. Engagement rings often include one or more diamonds. Following the marriage ceremony, the engagement ring may be worn in combination with a wedding band.

Introduction

In many human societies, the exchange of property or money around the time of marriage is socially expected and may take many forms (Fortunato et al. 2006). In the United States and some other industrialized economies, engagement rings are a form of marriage-related property transfer, usually from a man to a woman, that is conspicuous, financially costly, and socially meaningful. Beyond serving as a de facto signal of a woman's relationship status, an engagement

Engagement Rings as Signals

Engagement Rings as Signals Within the Relationship

Diamond companies and jewelers encourage the idea that a man should spend the equivalent of 2 months' salary on an engagement ring. Even when men do not follow that advice, the high cost of engagement rings has the potential to make them good opportunities for a prospective bride to assess her suitor's wealth. However, although it is true that wealthier men tend to purchase more expensive engagement rings than do their less wealthy counterparts, the relationship between male income and ring cost is not strong or consistent enough for it to serve as an effective signal of male wealth. Wealthy men often purchase rings that cost less relative to their income than do poorer men. Poorer men, on the other hand, often purchase rings that cost more relative to their incomes due to the baseline expense necessary to purchase an engagement ring at all and the availability of credit. Thus, anyone using an engagement ring to assess a male's resource control is likely to underestimate the wealth of a rich man and to overestimate the wealth of a poor man, making them rather misleading indicators of male resource control (Cronk and Dunham 2007; Dunham 2010). Fortunately, for prospective brides, women are likely to have plenty of other opportunities to assess the wealth of their suitors by the time that a proposal of marriage is made. In

cases in which an engagement ring is purchased from a couple's joint financial holdings, which happens frequently, the issue of the value of the ring as a signal of male resource control is moot (Dunham 2010).

Another possibility is that men may use engagement rings to enhance their desirability as marriage partners. This is supported by a recent study in which women indicated that they would be willing to accept an engagement ring of smaller size and lower cost in a hypothetical proposal of marriage from a man who was rated as highly attractive, in comparison to the size and cost of a ring that they would expect from a man who was considered less attractive (Cloud 2015). In another experimental study, participants expected men to spend more on engagement rings in settings with a male-biased sex ratio, consistent with the hypothesis that women can afford to be more choosy or can expect greater investment when single men are relatively plentiful (Griskevicius et al. 2012).

Camerer (1988) suggested that the high cost of an engagement ring may signal a man's commitment to the relationship. Thus, if long courtships are one signal of commitment to a relationship, an expensive ring might be particularly useful following a short one. Testing this within actual courtships, Cronk and Dunham (2007) found that shorter courtships were not associated with more expensive rings and thus that ring cost is unlikely to reassuringly signal commitment in the absence of a lengthy courtship.

The cost of an engagement ring may be associated with a woman's perceived desirability. Female youth is classically seen as a marker of fecundity and desirability, and research among the agropastoralist Kipsigis of Kenya demonstrated that younger women attracted larger bridewealths than did older women (Borgerhoff Mulder 1988). Similarly, younger women in a US sample received engagement rings that were proportionately more expensive, relative to male income, than did older women (Cronk and Dunham 2007). Furthermore, men in a psychological study indicated that they would hypothetically choose a more expensive engagement ring to propose to a woman who was considered highly

attractive than they would choose for a less attractive woman (Cloud 2015).

Engagement Rings as Signals Outside of the Relationship

In addition to signaling information between members of a couple, the gift of an engagement ring may signal information to outside parties. These parties include the kin and close social contacts of both members of the relationship, along with potential romantic rivals. Engagement rings may potentially serve a mate-guarding role wherein the conspicuousness of the ring signals to potential suitors that the wearer is in a committed relationship. Because the gift of an engagement ring creates an asymmetric signal in a heterosexual courtship, an engaged woman's relationship status can be ascertained simply by looking at her hand, whereas an engaged man's relationship status is only visually apparent if the members of the couple are seen together.

The gift of an engagement ring may signal the seriousness of the giver's intention to marry – and conversely, receiving the engagement ring may signal the recipient's intention in committing to her suitor – to social contacts who are invested in the well-being of the members of the couple, such as their kin and close friends. It may then serve a role of reassuring members of the couples' broader social circle and of facilitating multigenerational ties.

Marketing and Changing Norms

The convention of giving engagement rings upon a proposal of marriage may be affected by changing social norms. Jewelry wholesalers and retailers have a financial incentive to seek out new potential markets. One such opportunity comes through marketing fine jewelry to women to purchase for themselves. While the conventional notion is that an engagement ring is purchased by a man and presented to a woman at a surprise proposal of marriage, 16 % of couples in one study used the woman's funds to pay for part or all of the cost of an engagement ring, and women participated in the selection of the ring 42 % of the time (Dunham 2010). An advertising campaign launched in 2003 exhorted women to

“raise your right hand” and sought to increase purchases by women of diamond rings. The campaign promoted conspicuous consumption within the language of celebrating female empowerment, success, and self-worth and in doing so decoupled the association between diamond ring purchases and heterosexual marriage proposals (Crymble 2012).

Engagement rings are not exclusive to heterosexual relationships; indeed, among same-sex couples engaged to marry, two-thirds of female couples and nearly one-fifth of male couples purchased engagement rings (Wells 2014). In the aftermath of the recent US Supreme Court decision legalizing same-sex marriage nationwide, a possible further increase in same-sex marriage may involve further shifts in the engagement ring industry.

Conclusion

Engagement rings are considered to be a significant financial investment, yet have little intrinsic worth and a poor resale value. They are valuable because of what they signal and what they symbolically represent, rather than due to any advantage they confer to a couple embarking upon a new marriage. As a ritualized component of American courtship, engagement rings offer social scientists numerous remaining opportunities to test evolutionary hypotheses.

Engagement Rings as Modern Commitment Cue

Susan M. Hughes
Albright College, Reading, PA, USA

Synonyms

[Diamond rings](#); [Pledge to marry](#); [Wedding rings](#)

Definition

A ring that one partner gives to another when they become engaged to be married as a sign of their commitment.

Introduction

It is a common practice for a man to buy a relatively expensive engagement ring, usually including a diamond, to give to his fiancée when they become engaged as a symbol of their commitment and impending marriage. Engagement

rings are often donned for the mere intent to make public a couple's relationship commitment, and the woman, specifically, is to wear an engagement ring to display that she is "taken" and out of the dating market (Schweingruber et al. 2008). There seems to be no sex difference placed on the importance of an engagement ring before marriage (Ogletree 2010).

Signaling Mate Quality

The practice of giving and wearing a ring can also communicate a kind of social achievement (Parsons 2008) such that an engaged person possesses certain desirable attributes such as stability or maturity (Black and Monteverde 1975) that makes them a suitable, long-term mate. Some theorists have even proposed the so-called "wedding ring effect" whereby engaged individuals are thought to be preferred because being engaged signals their high mate value (Dugatkin 2000). Further, in cultures where it is customary for men to wear their wedding rings during their engagement, engaged men may be seen as attractive partners because it signals their willingness to commit to family life and invest time and effort in their children (Uller and Johansson 2003). Although there is mixed evidence that suggest wearing a ring makes a person more attractive to the opposite sex (Dugatkin 2000; Uller and Johansson 2003), wearing and advertising an engagement ring is still commonly exercised.

Cost-Benefit Analyses

The practice of giving engagement rings follows a reproductive cost/benefit analysis often seen in human mating strategies. A young male suitor will likely expend the costs of a diamond engagement ring against the expected gains of a joint union with a faithful mate and subsequent reproduction (Camerer 1988). A short-term relationship would not yield as much gain, and therefore, a man could not afford to make such a costly investment in those situations. Thus, premarital

gifts can be considered a way of sorting potential partners according to their intentions like investment plans.

In the past, marriage obligated women to bear children, which is very costly. A woman would have to determine who would be a worthy mate willing to invest and provision in her and her offspring, and the engagement ring can offer investment intent. Giving premarriage gifts such as engagement rings is thought to be analogous to the nests that male birds build to pledge their fidelity to female birds (Camerer 1988). Thus, presenting and accepting an engagement ring is a symbolic exchange that signifies commitment and trust from both partners (Haas and Deseran 1981). Despite the fact that marriage in modern times no longer obligates a woman socially or physically to bear children (due to changing mores, modern birth control, legalized abortion, etc.), gifts like diamond rings still send a resonating signal of intent and commitment.

Historically, engagement rings were given as long ago as the Middle Ages (Brinig 1990), but have become popular only recently. The custom of engagement rings in the United States has been traced back to the 1840s, but it was not until the early decades of the twentieth century that the practice became widespread (Rothman 1987). Before this time in the days of "Breach of Promise to Marry" laws, in most states it was possible for a woman to sue for damages in the event of a broken engagement (Brinig 1990). A woman would not only have lost her husband but it was thought that her mate value would have diminished if she relinquished her virginity to her fiancé before the wedding occurred. Hence, if a man did not fulfill his obligation to marry, the woman had legal recourse. The man did not have to pledge collateral since the law provided the woman with something akin to bankruptcy protection. Brinig (1990) argued that the elimination of such breach-of-promise actions in the mid-twentieth century created a demand for another bonding device, and she suggested that diamond engagement rings fulfilled that need. Women wanted upfront financial assurance, or collateral, from men so that if she never made it down the aisle, she would be left with something.

However, further reforms in family law began to insist that the ring is given conditioned on marriage and that it has to be returned if the marriage fails to materialize regardless of fault (Tushnet 1998). Thus, a woman's engagement ring became legally contractual and any breach of promise to marry requires the return of said engagement ring. Both the shift in mandatory ring-return rules and the denial of women's claims for restitution have made premarital law unfavorable to women, and engagement rings have spurred much litigation after the dissipation of an engagement before marriage (Tushnet 1998). To this day, more women than men, support the idea that women should be able to keep the ring after a break-up (Ogletree 2010). As a result of legal reformations, the diamond engagement ring has undergone a transformation and no longer stands for security but is meant for signaling commitment. As such, engagement rings have remained popular in the United States with more than three quarters of all first-time brides receiving them (Brinig 1990; Rothman 1987).

Diamond Engagement Rings

Modern opinions about the quality of a couples' relationship continue to be shaped by whether a man follows the traditional practice of bestowing a *diamond* engagement ring, in particular, to a woman. The wedding industry has bolstered the motto that "diamonds are forever." When surveying over 2,000 college students, participants perceived other couples' relationships as stronger when a diamond ring was presented during the proposal rather than another kind of ring or no ring at all (Schweingruber et al. 2008). Not presenting a diamond engagement ring, or giving another type of ring during a proposal, even if the woman wanted it, seemed to have caused confusion among a secondary audience evaluating another's proposal. The man was expected to present the woman with a diamond ring, and an absence of a diamond ring had casted doubt on whether the proposal was genuine. Interestingly, however, participants in the study did not perceive the strength of the relationship

differently based on the size of the diamond and had evaluated a relationship as stronger when the couple picked out the ring together as opposed to the man selecting the ring by himself.

The Expense of Engagement Rings

The lucrative wedding industry has also long promoted the norm that spending a large amount of money on an engagement ring is a true sign of commitment and is helpful for a marriage to be successful. However, there is no evidence to suggest that marriage duration is associated with the cost of the engagement ring or wedding ceremony. In fact, when examining more than 3,000 ever-married persons in the USA, it was found that after controlling for income and other characteristics among male respondents, relatively high spending on the engagement ring was *inversely* associated with marriage duration (Francis-Tan and Mialon 2015). The only positive factor associated with the cost of an engagement ring in proportion of male salary was with courtship duration, suggesting that engagement ring cost simply reinforces a signal of commitment already conveyed by a lengthy courtship (Dunham 2011).

Several factors related to a woman's mate value contribute to the amount a man will spend on an engagement ring. For instance, men who proposed marriage to younger women spent significantly more money on an engagement ring than men who proposed to older women (Cronk and Dunham 2007). The effect of female youth on ring cost is in line with many other studies that emphasized the importance of female age on male mate preferences (e.g., Grammer 1992), which makes evolutionary sense since female age is related to reproductive potential. Further, as men become older and acquire a higher income (and can likely afford more expensive engagement rings), they tend to seek younger mates (Grammer 1992).

While engagement ring cost is negatively associated with female age, it is positively associated with both male and female income (Cronk and Dunham 2007). That is, men who earned more money and whose fiancées earned more

money also spent more on engagement rings, further indicating that engagement ring cost may reflect both male and female mate value. Many studies (e.g., Hughes and Aung 2016; Pawłowski and Dunbar 1999) have found male income of primary importance for female mate preferences, which is consistent with the evolutionary hypothesis that females seek mates who have resources and are willing and able to invest in offspring. The effect of female income on ring cost suggests that female resource control also influences male mate choice similar to how bride wealth and dowry payments do in other societies (Gaulin and Boster 1990). Men may view female resource control as part of her mate quality, responding to the female's income itself, characteristics associated with income (e.g., her willingness and capacity to work hard), or some combination of the two (Cronk and Dunham 2007).

Because younger, uncommitted women value long-term mates who show wealth potential and provide them with romantic gifts (Hughes and Aung 2016), one can assume that the cost that a man spends on an engagement ring signals his economic accrual. Indeed, male income has the strongest effect on engagement ring cost (Cronk and Dunham 2007). While the price a man pays for a ring might not tell a woman anything more than she already knows about a man's income after a period of courtship, considering a man's overall spending habits relative to cost of the engagement ring he offers might give a woman valuable information about his willingness to invest in her and her offspring. Thus, bestowing an expensive engagement ring is revealing of not only his resources but also his generosity as a mate. In fact, men with low mate value can increase their own chances of attaining a higher mate value woman if they are capable and willing to share their resources (Grammer 1992).

Population Sex Ratios

Population sex ratio rates also affect spending patterns of engagement rings. A higher operational sex ratio (i.e., an abundance of eligible men in comparison to eligible women) permits women to become choosier and causes men

to invest more in mating effort. Thus, a male-biased sex ratio is associated with higher marriage rates, fewer out-of-wedlock births, greater paternal investment, and higher costs of engagement rings (see Griskevicius et al. 2012). When tested experimentally, both men and women expected men to spend more money on mating-related products such as engagement rings when women were scarce (Griskevicius et al. 2012). The authors concluded that a male-biased ratio should not only motivate men to exert more mating effort but also motivate women to increase their thresholds for what they consider is acceptable male spending on engagement rings.

Gender Roles

Lastly, stereotypical gender role attitudes play a part in the expectations of cost and value of commitment indicators such as engagement rings. It has been shown that traditional gender role attitudes were associated with the ideas of spending greater money on engagement rings rather than spending money more wisely elsewhere, and with the idea that only diamonds should be in engagement rings (Ogletree 2010). On the other hand, more egalitarian gender role attitudes were associated with less desire for high-cost engagement rings and weddings, yet did not devalue or eliminate the overall practice of having an engagement ring serve as an indicator of commitment.

Conclusion

An engagement ring is a piece of jewelry advertising that the person wearing it is engaged to be married. In many Western cultures, engagement rings are worn primarily by women and rings tend to feature diamonds or other precious gemstones. In some cultures, both men and women wear matching engagement rings and engagement rings are also used as wedding rings. Historically, a woman's engagement ring is presented as a token of a man's betrothal to his prospective spouse and represents a formal agreement to future marriage. The cost spent on

an engagement ring is related several to factors such as income level, age of the prospective bride, population sex ratios, and stereotypical gender roles.

The process of increasing women's willingness to engage in competition

Introduction

Competition among different species is one of the main structuring forces in the living world, shaping different ecological communities, while intraspecific competition is the main driving mechanisms behind natural selection in Darwin's theory of evolution, leading to fitness-enhancing

(Darwin 1872). However, individuals between and within species differ significantly in how much they invest into their competitive ability. While some individuals are very competitive in order to get access to high-quality resources, others prefer to avoid competition and make the most of lower-quality resources that are left over for them (Baldauf et al. 2014).

Competition levels also vary across sexes. Among humans, males are more competitive than females, reflecting different environmental pressures that both men and women have faced throughout human evolutionary history. Those differences have been addressed as a potential reason for the wage gap between men and women in which women receive less than men to perform the same function, when they are as qualified as their male pairs. Therefore, men would be better off if they were less competitive, whereas women would be better off if they were more competitive (Niederle and Vesterlund 2011). Increasing women willingness to enter competitions has been a challenge; however some scholars have presented some interventions that can enhance women's competitiveness, which would be addressed in this entry. Before discussing intervention strategies, I will first present potential evolutionary explanations to the difference between male and female competition levels, following with some empirical data comparing competitive behavior across sexes.

Women and Competition: Using the Past to Explain the Present

Darwin (1872) described man as "the rival of other men," adding that they delight in competition. In contrast, women are tenderer and less selfish, directing these qualities not only toward their infants but also probably toward their fellow creatures. Sexual selection is expected to have played an important role in shaping those differences. Because men have been forced to compete more fiercely for mating opportunities, considering that they have slightly greater reproductive gains to obtain from them, selection has not only shaped physical traits that favor men in contests

but also a psychology that makes them more willing to compete (Apicella and Dreber 2015). In contrast, although women do not lack motivation to compete, since they need resource as much as men do, especially when they have an offspring that depends on them, if they had competed as ferociously as their male pairs, they would have exposed themselves to death or injury, risking their ability to raise their children. Thereby, the ancestral women who avoided direct aggressive competition would have had more chances to raise surviving offspring (Campbell 2013). These different environmental pressures lead men and women to adopt different strategies to pass their genes ahead; while men had to compete in order to reproduce, women had to stay alive to raise their offspring, even if that meant giving up competing for better resources. Paraphrasing Campbell (2013), the message for women was clear "stay alive, at all costs."

Confirming those assumptions, the recent experimental economics literature has identified that men are more eager to compete and actively seek competition, whereas women tend to avoid it. For example, Buser (2012) found women less prone to enter a competition than men and identified biological differences as an important factor to explain gender preferences for competitiveness. More specifically, the results showed that women are substantially less competitive when taking contraceptives containing progesterone and estrogen and during the periods of their natural cycle in which the production of these hormones is higher. Consistent with an evolutionary explanation, these findings demonstrate that competitiveness is less desirable during infertile phase when the levels of these hormones are high than during the fertile phase when the hormones levels reach a low level.

Although men seem to be substantially more prone to compete than women, it is premature to conclude that women do not engage in competitive behavior. As stated previously in this entry, women have enough reasons to compete as much as do men. However, while competition among males is well documented, far less is known about female competition. The first reason for that is the already mentioned emphasis that sexual selection has attributed to male competition. Additionally,

when competing, women tend to do it in a subtler way in comparison to males whose competition tactics are overly expressed (Hardy 1981). For example, when competing for mates, having other women as opponents, to attract the desirable partner, differently from men, they would use strategies such as indirect aggression to decrease potential rivals' mate value (Vaillancourt and Sharma 2011). Indeed, overall, it seems that women are willing to engage in competition with other women, but on the other hand, when it comes to direct competition against men, they shy away from it even when they are high skilled. Perhaps the explanation for that lies on their own evolutionary past, because men tend to adopt more aggressive competition tactics, competing against them would be riskier than competing against other women.

In turn, although women compose the largest part of the population with a high education degree, men are still the ones who occupy the leadership positions, also receiving higher salaries than women to perform the same function. Traditionally, the explanation for that lies in gender roles and the discrimination women suffer in the labor market; however, as previously stated, the recent literature has also suggested that whereas men are eager to compete, women tend to avoid it. Many experimental and correlational studies have given support to that assumption, and even high-ability women choose not to compete, which is costly for the society that does not get to have their best members allocate into the positions they are suited for. However, as shown previously, the fact that women do not shy away from competition with other women suggests that they actually do not dislike competition; they perhaps only need the right motivation to display competitive behavior. In the next section, I will consider potential intervention that could improve women's competitiveness.

Strategies to Enhance Women's Competitiveness

Having that in mind, there is room for enhancing women's competitiveness. Analyzing the state of

the art of the gender competition gap, Nierdele and Vesterlund (2011) concluded that men would be better off if they were less competitive, whereas women would be better off if they were more competitive. Therefore, in order to increase women's competitiveness level, men's preferences for competitiveness should also be taken into account. A potential change would be to implement team competitions instead of single player competitions. An experiment showed that competing in teams reduces about two-thirds of the gender competition gap while at the same time reduces women undercompetition and men overcompetition since women prefer competing in teams, whereas men prefer competing individually.

Another potential intervention would be the adoption of affirmative actions to increase the engagement of women in tournaments and inhibit the interest of men. Nierdele and Vesterlund (2011) found that women were more willing to enter a tournament with multiple winners that guaranteed a minimum percentage of female winners. At the same time, the inclusion of the affirmative action did not affect negatively the participation of the best candidates, given that it encouraged particularly high-performing women to take part in the tournament. Another experiment also demonstrated that both offering women a preferential treatment by giving them a head start over men and the implementation of quotas contribute to increase women's willingness in engaging in a competition. Again, these actions did not affect negatively the entry of high-performing candidates.

Conclusion

In nature, enough resources are rarely available to fulfill the needs of the organisms. When resources such as food, mates, shelter, and safety are available in a short supply, competition arises. The same logic applies for humans, since men and women are constantly required to compete for several resources. However, in the evolutionary past of the species, those women who opt out direct contests could raise a larger number of children, whereas the male winners of

competition were the ones who had a higher reproductive success. As a result, avoiding competition was desirable for females, if they wanted to stay alive to raise their offspring, while for males, competing was crucial to acquire better mating opportunities and reproduce. Nowadays, the environment is not as harsh as was in the past, women can easily avoid a pregnancy, and in most countries, they can count with support from the state to raise their children. On the other hand, men are no longer required to engage in aggressive contests to obtain a mate or to guarantee other resources. These environmental conditions, however, have not been in motion for long enough to disrupt the long evolutionary chain, and as such, humans still express traits that helped their ancestors to survive thousands of years ago. Women are still avoiding direct competition, yet men are more prone to compete.

While in the past avoiding competition benefited women, nowadays this can bring some disadvantages that, as stated in this entry, have been shown in the literature to reflect in a wave gap between men and women. A substantial experimental evidence has demonstrated that women shy away from competition, whereas men tend to seek for it. Women, however, do not avoid competition when their opponents are other women, perhaps because women competition tactics are less ferocious than men's, which suggests that women actually do not dislike competition as thought for many researchers, but they evaluate the risks before they decide to engage in a competition. In fact, women need resources as much as men do; however they seem to be more cautious and evaluate the risks and benefits before competing.

Based on that, some actions can be adopted in order to increase women's competitiveness. The actions suggested in this entry were the implementation of team competition instead of individual competition and the adoption of affirmative actions such as requiring a minimum percentage of female winners or giving women a start advantage over men. All these actions seem to be useful to increase women's competitiveness and, at the same time, in selecting high-performing individuals to enter competitions. Such strategies could be implemented, for example, by companies to assure that qualified individuals from both sexes

fill in the vacancies they are suited for and, as such, decrease the wave gap between sexes.

Definition

“Enlarge the shadow of future” is one of the recommendations given by Robert Axelrod (1984) to help promote cooperation in social dilemmas, based on evolutionary models.

Introduction

Based on evolutionary models of cooperation and computer simulations, Axelrod (1984) proposed three mechanisms to promote cooperation between selfish individuals: (a) make future outcomes more important than the present ones, (b) change payoffs of possible outcomes in an interaction, and (c) teach people to care about others. This entry concerns the first of these mechanisms, which refers to the increase of the likelihood of future interaction with others and is called “the shadow of the future” by Axelrod and others (Axelrod 1984; Axelrod and Dion 1988; Bó 2005; Oates et al. 2010b; Sebastián-Enesco and Warneken 2015).

Evolutionary Models of Cooperation

Cooperation, or altruism, has long been considered an evolutionary puzzle (Nowak 2006). If one assumes that natural selection will tend to favor selfish strategies in a population, how could cooperative strategies have evolved? A solution to this problem was the kin selection theory (Hamilton 1964) which demonstrated that individuals will tend to cooperate with closer kin, because the cooperators’ genes will be transmitted indirectly through their relatives. However, this theory does not fully explain why some animals, and specially humans, cooperate with nonrelatives. Thus, a second solution to the puzzle of cooperation was the theory of reciprocal altruism (Trivers 1971). This theory proposes that cooperation can evolve if there is a high chance that the individual’s actions will be reciprocated in the future. The theories of indirect reciprocity (Alexander 1985) and network reciprocity (Nowak 2006) contribute to this framework by adding that this return can come from third

parties and not necessarily from the individual who benefited from the altruistic act in the first place.

Axelrod (1984) modeled repeated pairwise reciprocal interactions to investigate whether and how cooperative strategies would evolve among a variety of other strategies. He and his collaborators (Axelrod 1984; Axelrod and Dion 1988) ran a series of computer tournaments in which several game theorists submitted their strategies to compete against each other in repeated rounds of an economic game called the prisoner’s dilemma. This game simulates a social dilemma in which an individual is always better off in the short term if he chooses to not cooperate with others. This dilemma is illustrated in the following way: two accomplices are arrested, hence becoming prisoners. They are put in separate rooms and cannot communicate with each other. They can either confess and receive a lighter sentence or remain silent and receive a harsher one. Regardless of which one decides, the confession always remains the best choice, if the individuals involved will never meet again. However, when there is a high chance of future interaction, remaining silent, and therefore cooperating with the other criminal, might be more important for the long term.

In Axelrod’s tournaments, the programmed strategies interacted repeatedly with each other, with some of them choosing always the same strategy (e.g., always defect or always cooperate) and some of them using some sort of decision criteria. The strategies could win points by either choosing to cooperate with or defect against their partners in each round, and the payoffs were dependent on both their decisions and those of their partners. The strategies that won more points in the long run would survive and reproduce more than (i.e., out-compete) the other strategies. The winning strategy in the first tournaments was the tit for tat, which had a simple heuristic: always cooperate in the first move and replicate the other player’s previous move – that is, cooperate when someone had cooperated previously and retaliate when someone had defected previously. Thus, in a mixed strategy population, tit for tat can survive and spread. But this will only happen if the shadow of the future is large enough, so that tit for tat can capitalize on the risk of cooperating

with potential defectors. Other tournaments (Axelrod and Dion 1988; Wedekind and Milinski 1996) also showed that tit for tat loses to other more forgiving strategies, but only after winning over all the other previous ones. Thus, the better strategy for cooperation in repeated social dilemmas with the same partners involves a combination of being a bit generous, thus giving others the chance to change their strategy and engage in cooperation while still eventually punishing those who refuse to cooperate.

There are two main types of models that attempt to explain the evolution of cooperation: partner control models, in which cooperators can attempt to control their partners by cooperating with other cooperators and cheat or punish noncooperators (Axelrod 1984; Trivers 1971), and/or partner choice models in which cooperators can choose their partners, thus preferring to interact with other cooperators (Baumard et al. 2013; Noë and Hammerstein 1994). The shadow of the future is especially relevant to the former type of model, which accounts for situations in which individuals technically can't choose with whom they interact. Thus, if the probability of encountering the same partners is relatively high, making future interactions more predictable, and in the long run the benefits of cooperating with others surpass those of cheating, individuals will tend to cooperate with each other. Moreover, in real-world situations similar to the prisoner's dilemma, increasing the chances of meeting the same people in the future increases the probability of cooperating with them, more specifically when these repetitions appear infinite – that is, with no clear indication of when the last interaction between partners will occur (Bó 2005). Thus, enlarging the shadow of future is a recommendation applied to contexts in which cooperation is not always desirable, and individuals cannot choose with whom they interact with based on past interactions or any other judgment.

For the shadow of future to be effective, individuals must be able to respond to environmental or social cues that hint on the likelihood of meeting their partners again. This can happen through simple mechanisms, such as territoriality (individuals interact with others in fixed territories, thus

ensuring that the same individuals will meet periodically, Axelrod and Hamilton 1981) or cooperation with partners that are similar to themselves in some manner (Axelrod and Hamilton 1981; Riolo et al. 2001). However, more sophisticated skills are required for more complex interactions, such as the ability of recognizing others and remembering past interactions (Stevens et al. 2005). In all of the cases outlined above, the shadow of future can maintain cooperative relationships because these mechanisms ensure that noncooperators can be retaliated by desertion or punishment. The following sections present examples of the influence of the shadow of the future on nonhuman animal and human social interactions and lay out the limitations of the shadow of the future as a mechanism to promote cooperative behavior.

The Shadow of the Future in Nonhuman Animals

There are several examples of reciprocal interactions among nonhuman animals which are affected by the shadow of the future (Axelrod and Hamilton 1981; Buss 2008; Oates et al. 2010b; Trivers 1971). The vampire bat is a classic example of reciprocal altruism (Carter and Wilkinson 2013; Trivers 1971; Wilkinson 1984). Vampire bats live in small communities of females and their offspring and feed themselves in the night, by sucking the blood of other animals. Feeding is very costly to them, due to higher rates of failure. To overcome this, vampire bats regurgitate blood and share it with those that had given blood to themselves previously, hence favoring reciprocal interactions. In addition, bats only share blood with individuals with whom they had frequent interactions previously and share more often with those who helped them recently. Thus, it pays off for them share blood with those in need, because the chances that the favor will be reciprocated in the future are high.

The mutualistic relationship between the cleaner fish and its clients is another good example of reciprocal altruism, which occurs between species, and it is kept by means of territoriality cues (Axelrod and Hamilton 1981) and indirect reciprocity (Bshary and Grutter 2006). Cleaner fish feed themselves off parasites they remove from

other fish's and reptiles' bodies; large fish are potential predators for the cleaners, which are very small, but the clients avoid eating them because of the benefits of the removal of parasites. A species of cleaner fish that remains in small areas (called cleaning stations) tend to cheat their clients less than another species that rovers over a larger area, which makes it possible for them to desert clients more often (Oates et al. 2010a,b). Despite that, the latter also has preferred areas for interacting with specific clients, more specifically where there is a higher probability of future repeated interactions, which indicates that they also establish stable reciprocal relationships and are affected by the shadow of the future (Oates et al. 2010b).

The Shadow of the Future in Humans

The social contract theory (Cosmides and Tooby 1992) proposes basic adaptations for reciprocal cooperative interactions in humans. Based on findings from experiments with a logic task applied to social contexts, Cosmides and Tooby (1992) proposed that humans have psychological adaptations to detect cheaters in social exchanges. They identified the risk of being exploited by cheaters as the main source of evolved adaptations for cooperation; in response to that, humans have developed: the ability to recognize different individuals, to remember past interactions, to communicate their values, to model others' values, and to represent costs and benefits across different kinds of items. In other words, human have evolved a set of skills necessary for engaging in more sophisticated cooperative reciprocal interactions than other animals.

Humans engage in reciprocal interactions very early, more specifically by turn-taking interactions initiated by parents (Trevvarthen 2011). There is evidence that these interactions increase prosocial behavior in young children (Cortes Barragan and Dweck 2014; Rabinowitch and Meltzoff 2017), which can be an indication of an early mechanism that responds to cues of future interactions. In other words, repeated interactions might hint at future probability of interactions, thus functioning as a cue for prosocial behavior. However, reciprocal prosocial behavior, such as taking turns in sharing goods with a partner, only seems to fully emerge during middle childhood. Five-year-old American

children are able to delay gratification and share more goods with a partner in anticipation of future reciprocal interactions (House et al. 2013; Sebastián-Enesco and Warneken 2015). Eleven-year-old American children increased their donations in repeated prisoner's dilemma games compared to one-off games (Blake et al. 2015). However, when in repeated interactions within a group, children's donations tend to decrease with time when they are anonymous but not when they are public, especially among children older than 8 across different cultures (Dutra et al. 2018; Zbaratany et al. 1985) and similarly to adults (Bó 2005; Wang et al. 2017). Thus, the shadow of the future increases human prosocial behavior, but particularly when individuals make public decisions.

Limitations to the Shadow of the Future

Enlarging the shadow of future refers to the increase of frequency of interactions and commitment between partners. However, this recommendation is based on models of reciprocal altruism which often assume that players have similar levels of power, cannot communicate with each other, and cannot opt completely out of the game (Buss 2000). Whenever one of these conditions is not met, enlarging the shadow of the future might not be as effective or even necessary. For instance, Ostrom (2000) found that communication can increase cooperation in collective social dilemmas similar to the public goods games, up until the last interaction, being more effective than external incentives or norms in similar settings.

Conclusion

Empirical evidence supports classical theoretical predictions that enlarging the shadow of the future – that is, increasing the probability of interacting with others in the future – is one significant factor in the increase of cooperation among partners in the long run. However, the influence of future interactions is constrained by certain conditions, such as individuals' abilities to detect and interact with cooperative partners, environmental conditions that limit social interactions to certain areas and increase contact among individuals. Many human

interactions are either one-off, or future interactions are uncertain, particularly in contemporary societies; other mechanisms such reputation and social control from institutions are in place to enforce cooperation among humans. Nevertheless, whenever the shadow of the future is large enough and individuals are able to retaliate by not cooperating with noncooperators, cooperation thrives.

Synonyms

Danger; Rate of death and disability; Risk

Definition

Environmental harshness: externally caused levels of morbidity and mortality in a population.

Introduction

Environmental harshness is one of the major components of an ecology implicated in guiding an organism's life history decisions. As such, an organism's experience with cues of harshness in an environment during critical periods of ontogeny is capable of modifying developmental trajectories and energy budget tradeoffs (Ellis et al. 2009). In humans, encountering harshness and unpredictability has also been revealed to predispose an individual to a suite of psychological tendencies: impulsivity, risk-taking, and the propensity to discount delayed rewards (Griskevicius et al. 2011b, 2013). Harshness emerges as a principal characteristic of an ecology's profile that predicts both between-species and within-species variation in life history strategies (Ellis et al. 2009).

Extrinsic Threats Versus Intrinsic Threats

The external threats of morbidity and mortality that together comprise an environment's level of harshness can be either extrinsic or intrinsic. This definition is not solely determined by the source of death and disability (e.g., violence, disease, or famine), but rather an organism's ability to overcome such threats by optimally investing resources and effort (Ellis et al. 2009). For extrinsic threats, allocating additional resources towards mitigating the impact of environmental harshness through parental effort or somatic development fails to reduce morbidity and mortality. As a result, organisms inhabiting a harsh ecology dense in extrinsic threats typically display phenotypes representing tradeoffs that favor reproductive investment, such as reproducing at a younger age, a greater quantity of offspring, a smaller size, and reduced parental effort (Kaplan and Gangestad 2005; Mittal and Griskevicius 2014). This faster strategy is employed to maximize the probability that at least some of the many – albeit lower quality – offspring will reach reproductive age. Conversely, environments dominated by intrinsic threats in which rates of morbidity and mortality are sensitive to somatic investment might actually select for slower life history strategies. In this case, increased parental investment and a longer adolescence yield a lower quantity of high-quality progeny better equipped to survive and reproduce.

Harshness in Nonhuman Animals

Many characteristics of an ecology can influence rates of death and disability in a population. Among these are predation, pathogen density, and bioenergetic resource availability, alongside other sources of environmental stress (Ellis et al. 2009). The effects of harshness on life history strategies in nonhuman animals have been verified both in the wild and under controlled laboratory conditions. For example, organisms inhabiting regions of high predation – an extrinsic threat – exhibit traits at the faster end of the life history continuum than conspecifics in areas with less predation (Reznick

and Endler 1982). In contrast, intrinsic threats that can be diminished by investment in traits, like a larger size, facilitate resource allocation towards higher quality offspring, driving slower life history strategies (Gosselin and Rehak 2007).

Harshness in Humans

The ancestral environments of humans have likewise demanded the evolution of mechanisms for overcoming harshness. External threats to survival and reproduction in human ecologies resemble those of other species, including disease, conspecific violence, and resource scarcity. For instance, crosscultural research has found that parental investment is lower when pathogens in a region are extremely dense (Quinlan 2007). In addition to the threat of disease, comparison of crime and reproductive age in different counties of the United States confirmed that mortality risk by violent crime rates predicted an earlier age at first reproduction, also demonstrative of a faster life history strategy (Griskevicius et al. 2011a). Elaborating upon this finding, experimental studies have supported the impact of mortality threats on human life history strategies. For example, priming individuals with environmental danger led those having experienced a lower childhood socioeconomic status (SES) – a proxy measure of environmental harshness and resource scarcity – to report a desire to reproduce sooner than individuals with a higher childhood SES.

Psychological Effects of Harshness in Humans

In addition to changes in reproductive behavior and physical maturation, levels of environmental harshness can further impact human psychology. Much research has explored psychological and cognitive shifts that might accompany or mediate changes in development and behavior induced by harshness. When faced with mortality cues, individuals having experienced a lower childhood SES tend to prefer riskier decisions for larger

payoffs and discount the future compared to their higher childhood SES peers (Griskevicius et al. 2011b). Priming another facet of environmental harshness, resource scarcity, similarly led individuals from a lower childhood SES to prefer risk, respond more impulsively, and more quickly approach temptation (Griskevicius et al. 2013). In the same way an organism may forgo extended development to maximize fitness by reproducing earlier in a harsh ecology, these psychological reactions to mortality threats may serve an adaptive function. Although impulsivity and risk-taking could be considered harmful or counterproductive in modern environments, they may have been integral in maintaining adequate bioenergetic reserves and escaping danger in the past.

Critical Periods

The effect of context in calibrating life history strategies appears to be most influential during critical periods of development. Many of the changes in behavior and psychology predicted by childhood conditions are not replicated when considering only adult environments (Ellis et al. 2009; Griskevicius et al. 2011; Simpson et al. 2012). This window of susceptibility during which environmental harshness is most important in adjusting life history strategies appears to exist during early childhood, resembling critical periods of development for other important functions, such as language acquisition.

Unpredictability

Unpredictability in environmental harshness is defined as the temporal-spatial variation in levels of harshness (Ellis et al. 2009). In addition to total harshness in an ecology, instability in conditions impacts parental investment, reproductive behavior, and other components of a life history strategy. Research suggests that this role of unpredictability in shaping life histories is independent of absolute harshness. For example, experimentally generated volatility of foraging

conditions in nonhuman primates reduced parental investment more than mere foraging harshness (Rosenblum and Paully 1984). Further evidence in humans using a longitudinal analysis of environmental unpredictability in childhood and adult outcomes revealed that sources of early life unpredictability, such as number of residential transitions and mother's employment status changes, predicted risky behavior in adulthood (Simpson et al. 2012). Psychological responses to unpredictability likely appear because risks that cannot be anticipated cannot be minimized through appropriate somatic investment. Therefore, stochasticity in an ecology itself presents an extrinsic challenge to survival and reproduction.

Conclusion

Environmental harshness and unpredictability are key factors in the calibration of life history strategies for humans and other organisms. Threats of morbidity and mortality in an ecology necessitate mechanisms of diverting resources towards investment in allaying risk if possible, or expediting reproduction if not. The formative years of early childhood represent a crucial window for role of harshness in developmental programming. Further research is warranted into the budget tradeoffs that are made in different domains when an organism is faced with varying levels of environmental harshness. Future lines of inquiry will also examine the pathways through which organisms receive cues about the quality of the local ecology.

Definition

Environmental harshness is the surrounding condition an individual is living in, which can be measured, for example, by local mortality/morbidity and availability of the resources.

Introduction

There are many influences on pair-bonding in human and nonhuman animals alike, and one of them is the harshness of the environment the pair is living in. Environmental harshness and local mortality can affect an individual's mating strategy, which is closely intertwined with pair-bond stability. In harsh environments, reproductive strategies are often characterized by prioritization of mating over parenting effort (Ellis et al. 2009), which can result in infidelity and relationship dissolution. It is possible that relationship instability, and a greater need for biparental care in harsh conditions, relates to what individuals find initially attractive in a prospective mate as well, shifting the preference away from what is stereotypically considered as attractive.

Life History Theory, Mating Strategies, and Pair-Bond Stability

Non-evolutionarily informed research has found that poverty, low educational levels, and unemployment are important risk factors for divorce (Amato 2010). From evolutionary point of view, all of these can be used as an indicator of the harshness of the surrounding environment. The effect of environmental harshness and mortality on pair-bond stability can be understood within the life history theory (LHT) framework. According to LHT, in harsh, high mortality environment, it may be more adaptive to follow a fast life history strategy (LHS), with early sexual maturation, early sexual activity, and a larger quantity of offspring that receive less parental care.

The effects of environmental harshness can have a sex-specific impact on a mating strategy. For men, fast LHS is often associated with a higher likelihood

for deserting their partner while looking for new mating opportunities elsewhere. For women, fast LHS may relate to an earlier age of childbearing and bringing up children without a stable, long-term father figure in the household (Nettle 2010). Indeed, when looking for long-term partners, environmental harshness is associated with a preference for a mate that is less likely to be unfaithful.

Research on long-term mate preferences has found that in harsh environments, both sexes prefer partners that do not exhibit exaggerated sexually dimorphic traits that are attractive to the opposite sex. For women, this may indicate a preference for lower levels of facial masculinity in men, and for men, lower levels of facial femininity in women (e.g., Little et al. 2007; Lyons et al. 2016; Marcinkowska et al. 2014). It is possible that preferring a lower-quality but higher investing partner could work as an insurance policy against desertion in harsh conditions.

Conclusion

Environmental harshness can affect pair-bond stability via a shift in mating strategies, where individuals may prioritize mating effort over parenting. Fast LHS can be adaptive in high mortality environments, with the cost of reducing the stability of a pair-bond. In harsh conditions, children are more likely to grow up in a household where the biological father is absent, as fast LHS in men is associated with promiscuous mating strategies. Environmental harshness has also an impact on mate attraction, where less attractive individuals are preferred as partners, possibly due to a lower likelihood of infidelity.

Definition

The external circumstances, objects, or conditions that influence one's pubertal maturation.

Introduction

There is a large and growing body of research on the environmental influences affecting pubertal maturation, leaving little uncertainty regarding its significant role in pubertal onset. Research on secular trends regarding puberty has shown a steady decrease in the age of onset from the mid-nineteenth to the mid-twentieth century in developed countries (Parent et al. 2003). Research such as this indicates that environmental factors must play a role in pubertal maturation, given the short time frame for such drastic changes. This entry focuses on the environmental influences regarding the topic of pubertal maturation through aspects pertaining to (1) energetics, (2) psychosocial stressors, and (3) endocrine disrupting chemicals. It is important to note, however, that due to the limited research on male pubertal maturation and difficulties associated with it, this entry will focus mainly on the environmental influences affecting the pubertal maturation of females.

Energetics

Energetics theory hypothesizes that the degree of nutritional availability in one's environment affects one's pubertal development (Ellis 2004). As such, “children who experience chronically poor nutritional environments will experience late pubertal development. . . , whereas children who experience chronically rich environments will experience early pubertal development. . . ” (Ellis 2004, p. 925). Although the theory holds that the greater the surplus of metabolic energy that can be garnered then the greater the surplus for development and reproduction, it has little effect on sufficiently nourished populations (Ellis 2004). However, prepubertal females from less developed countries who were adopted (or migrated) into first-world countries tend to experience menarche at an earlier age (Parent et al. 2003). This phenomenon is speculated to be a result of one moving from an underprivileged environment to a privileged one, causing the body to undergo a period of *catch-up growing*, which triggers sexual maturation

(Karapanou and Papadimitriou 2010). In a somewhat similar manner, one's socioeconomic status (SES) may also influence the onset of one's pubertal maturation. For instance, females from "higher social classes experience earlier pubertal development than do girls from lower social classes" (Ellis 2004, p. 926). Generally, however, this is only evident in societies where significant differences in health and nutritional status between low- and high-SES individuals exist (Ellis 2004).

While there are many possible compounding factors that may be responsible for the association between SES and the onset of puberty, it is likely that the two associated with nutrition – diet and exercise – play an influential role. Typically, individuals lower in SES, among other things, are limited in their options regarding diet and exercise. Research has shown that prepubertal females between the ages of 3–5 years old, whose diets are high in animal protein, tend to experience earlier menarche than those whose diets are high in plant protein (Karapanou and Papadimitriou 2010). Similarly, prepubertal females whose diets are high in fiber have also been associated with delayed onset of puberty (Ellis 2004). Additionally, diets high in soybean products, fortified products with supplements like dietary fiber, calcium, and vitamin D may also be influential in the timing of female sexual maturation (Yermachenko and Dvornyk 2014, p. 5). In addition to diet, a child's weight has also been found to be correlated with pubertal timing (Karapanou and Papadimitriou 2010). In females, early menarche becomes increasingly likely the greater their subcutaneous fat levels and BMI are during prepubertal ages. On the other hand, leanness has been correlated with earlier puberty in males (Karapanou and Papadimitriou 2010).

A factor worth noting, when considering nutrition and diet, is energy expenditure. Exercise, which plays a crucial role in the body's allocation of caloric intake, has been shown to delay the onset of menarche in females (Karapanou and Papadimitriou 2010). However, this typically only occurs with those who conduct at least 2 h of daily physical activity, such as athletes (Karapanou and Papadimitriou 2010).

Psychosocial Stressors

Since 1991, when Belsky and colleagues published the evolutionary theory of socialization, there has been a great deal of research conducted into the associations between various psychosocial stressors early in life and pubertal timing (Ellis 2004). While there is a general consensus regarding the most sensitive period of exposure to psychosocial stressors being the first 5–7 years of life, there is conflicting findings on the degrees of significance. These contradictory findings may be attributable to likely co-occurrences between many of the stressors (Ellis 2004), possible cumulative effects of co-occurrence (Li et al. 2014), other variations in the environment and/or racial/genetic dispositions (Ellis 2004; Li et al. 2014), or differences in study methodology (Ellis 2004). Nonetheless, most converging empirical research seems to be indicative of reasonable, yet incomplete, support for a number of psychosocial stressors influencing puberty (Ellis 2004).

Converging empirical evidence, viewed as supportive of psychosocial stressors' influence on puberty maturation, pertain to various aspects of familial environment and childhood adversities (Li et al. 2014; Ellis 2004; Yermachenko and Dvornyk 2014; Karapanou and Papadimitriou 2010). Based on his comprehensive literature review, Ellis found "Empirical research to date had provided 'reasonable, yet incomplete. . .' support for [psychosocial acceleration theory] 'warm, cohesive family environments slowing down pubertal development'" (Ellis 2004, p. 935). Although he found an association between greater frequency of parent-child interactions being predictive of later puberty, he failed to find adequate methodologically sound research suggesting the opposite true of dangerous or conflictual family environments predicting earlier pubertal development (Ellis 2004). Studies on the roles of various forms of familial conflict and their association with the timing of puberty exposed great gaps in knowledge leaving research riddled with inconsistent findings (Li et al. 2014).

Some of the more consistent and accepted associations among familial environments and childhood adversity for the onset of female menarche are seen with marital dissatisfaction,

parental mood disorders and illness, sexual abuse, parental investment, neglect, physical abuse, father presence/absence, stepfather presence, step-brother presence, family size, number of older sisters, urban or rural environment, and many others (Ellis 2004; Karapanou and Papadimitriou 2010; Li et al. 2014; Yermachenko and Dvornyk 2014). Some of these instances have also been associated with accelerated pubertal development in males (Li et al. 2014). Depending on an individual's genetic predisposition to stress, the age of occurrence, duration, and frequency, psychosocial stressors such as sexual abuse have been thought to have associations with both late and early puberty. Further evidence for genetic disposition is seen in research showing father absence having less of an effect on African-American females, regardless of age of occurrence, indicating the significance of race. Combinations of psychosocial stressors can also alter data as seen by prevalence of early menarche becoming "...even higher when stepfather presence is combined with a stressful family environment and with maternal mood disorders" (Karapanou and Papadimitriou 2010, p. 5).

Specific factors like severe socioemotional stress or war are thought to largely include prolonged psychological stress. While there is little doubt of the association between times of war and pubertal delay, there is some regarding the specific causes of the delay. Many of the confounding variables (food rationing, increased physical activity, prevalence of disease, etc.), make it difficult to ascertain the mechanisms for this delay (Ellis 2004).

Endocrine Disrupting Chemicals

Since the 1940s, there has been an exponential increase of synthetic chemicals found in the environment, with roughly more than 84,000 different chemicals in commerce (Meeker 2012). Many of these synthetic chemicals, as well as natural chemicals found in nature, can interfere with hormonal pathways through a variety of mechanisms that interfere with endogenous endocrine action

(Zawatski and Lee 2013). These endocrine-disrupting chemicals (EDC) can "compete for estrogen receptor binding and activation, interfere with post-receptor signaling pathways, and modulate synthesis, bioactivity, or degradation of hormones, receptors and cofactors" (Zawatski and Lee 2013, p. 3). Through these mechanisms, and their influence on a range of different hormones responsible for the development of reproductive organs (e.g., estrogens, androgens, and gonadotropin-releasing hormone), it is speculated that EDCs can affect pubertal maturation, among other aspects of human development (Zawatski and Lee 2013; Meeker 2012; Özen and Darcan 2011). The cause for concern and relevance to pubertal development comes from the degree to which the average person is exposed to EDCs. Many EDCs are commonly found in consumer goods, personal care products, food, water, contaminated soil, and air (Zawatski and Lee 2013; Meeker 2012). Some of this EDC exposure is due to highly toxic chemicals, such as Dichlorodiphenyltrichloroethane (DDT) and Polychlorinated biphenyls (PCBs), which were banned in industrialized nations in the 1970s, but are still detectable in the environment (Zawatski and Lee 2013). These persistent organic pollutants (POP) are "lipophilic chemicals with long half-lives that bioaccumulate up the food chain" (Meeker 2012, p. 953). POPs, along with most other EDCs, accumulate in fat tissue, are difficult to deactivate and are likely to stay within the human body for long periods of time which may have deleterious effects (Özen and Darcan 2011). Dose, duration, and age of exposure also have roles in the possible effects EDCs may have (Özen and Darcan 2011). Evidence of this is found in research affecting females who experience prenatal exposure as well as exposure via lactation to polybrominated biphenyls (PBB) and DDE/DDT (Özen and Darcan 2011; Den Hond and Schoeters 2006). Further compounding onto the complexity and difficulties associated with EDCs are the long latency periods between exposure and effect, multiple mechanisms a single chemical can use, individuals' genetic susceptibility, exposure to multiple chemicals, and other environmental influences.

Although limited, human studies pertaining to the effects of EDCs on puberty have been documented and supported by evidence gathered in animal studies (Karapanou and Papadimitriou 2010; Meeker 2012; Özen and Darcan 2011; Yermachenko and Dvornyk 2014; Zawatski and Lee 2013). Due to animals' serving as a baseline and reference point, it is reasonable to conclude that a relationship between EDCs and pubertal timing exist (Zawatski and Lee 2013). Several studies on postnatal female exposure have shown the risk of early menarche to increase with high exposure to PCB, DDE, and other EDCs, while delaying age of menarche with high levels of lead exposure (Den Hond and Schoeters 2006; Yermachenko and Dvornyk 2014). Findings pertaining to some exposures in prepubertal males found similar results. There is an association between earlier pubertal onset and exposure to DDE and PCB (Zawatski and Lee 2013), while lead and certain pesticides (specifically, endosulfan) have been associated with delayed puberty and decreased penile length (Hond and Schoeters 2006). Although many of these findings have been confirmed in animal studies, the various confounding influences still pose a significant challenge for uncovering the effects of EDCs on pubertal development.

Conclusion

A general consensus among various nations attributes approximately 50% of the variation in age of menarche to environmental influences (Ellis 2004). These influences pertain to energetics (e.g., nutrition, weight, diet, exercise), psychosocial issues (e.g., family environment, childhood adversity, and war), as well as EDCs (e.g., DDT, PCB). Additionally, environmental influences such as SES, migration, war, several psychosocial stressors, premature birth and birthweight (associated with greater risk for menarche), and illness covary with multiple aspects.

Research into associations between various environmental influences each have their own difficulties. Dose, duration, and age of exposure also play crucial roles in the possible energetic

(e.g., energy expenditure), psychosocial (e.g., length of abuse), and EDC effects. Additional challenges regarding EDCs are the long latency periods between exposure and effect, multiple mechanisms a single chemical can use, individuals' genetic susceptibility, exposure to multiple chemicals, and other environmental influences. These problems increase the difficulty of understanding how various environmental factors affect the human pubertal process. Further research is needed in many areas of environmental influence on pubertal maturation.

Definition

Within the life history theoretical framework, environmental risks refer to depleting or low levels of resource and high rates of extrinsic threats, such as predation, famine, disease, and intraspecific violence, that are insensitive to the survival effort of the individuals and that cause mortality and morbidity of the population, as well as stochastic variations of the resource levels and mortality–morbidity rates.

Introduction

Hence, as more individuals are produced than can possibly survive, there must in every case be a struggle for existence, either one individual with another of the same species, or with the individuals of distinct species, or with the physical conditions of life. (Darwin 1859/1979, p. 117)

In the chapter entitled “Struggle for Existence” of *The Origin of Species*, Darwin points out a critical assumption about evolution – that there will always be more lives than there are resources to support them. This results in constant intra- and interspecies competition in which only the fittest survive. The competition or struggle for existence occurs at the individual or organism level and, fundamentally, at the genetic level. However, advancements in knowledge since Darwin’s seminal work was published have shown further evidence that an individual’s life is composed of characteristics called life history (LH) traits. Limited resources and resource competition manifest as a limited energy budget that cannot support all LH traits, and the strategic allocation of limited energy results in trade-offs between different LH traits. Similarities and patterns derived from LH trade-offs form LH strategies, which are aimed at optimizing the struggle for existence at the individual level. One such broad pattern of LH trade-offs is the fast–slow LH strategic continuum (Promislow and Harvey 1990). A fast LH strategy involves trade-offs characterized by early maturation and reproduction, squandering rather than conserving energy and resources, and high mating and low parenting. By contrast, a slow LH strategy involves late maturation, delayed reproduction, slow development, and a longer lifespan, all of which facilitate amassing and conserving resources, learning and developing skills, and parenting and training fewer, high-quality offspring who are equipped for intra- and interspecies competition in the struggle for existence. The fast–slow continuum and other intraindividual strategic LH trade-offs respond to and are shaped by the struggle for existence at the individual level. This chapter addresses the relationship between the

environmental risks or constraints that make individuals' lives a struggle and the intraindividual LH strategic trade-offs individuals employ to optimize the conditions of the struggle for existence.

Environmental Harshness

What is essential for life and subsequently responsible for the struggle for existence? The answer must be food and safety, the levels and variations of which also shape LH trade-off strategies. For most species and for humans of the evolutionary past, the main safety concern is predatory risk, which is the main cause of mortality. Other extrinsic causes of mortality include famine, disease, and conspecific violence. Because these causes may also lead to injury, illness, and disability, in addition to death, Ellis et al. (2009) coined the term "mortality–morbidity" to encompass all of these negative consequences of such extrinsic risks as predation and disease. Food, or more generally, resources are essential for life. Their shortage and scarcity is responsible for the struggle for existence. In the evolution literature, resource scarcity and mortality–morbidity are defined as constituting the harshness dimension of the environment that regulates fast–slow LH strategies (Ellis et al. 2009).

Resource Scarcity

Resources were first studied as a density-dependent selection condition in relation to population density and competition (MacArthur and Wilson 1967). When resources are sufficient to carry or support organisms living in a habitat, organisms tend to freely exploit them for fast development and early reproduction, producing high numbers of offspring who receive little parental investment in teaching and learning about survival because they can survive and thrive in resource-rich and competition-free environments (Pianka 1970). This is known as r selection, where r represents the maximal reproductive rate of a species (MacArthur and Wilson 1967). When the high reproductive rate increases

the population density to the point that resources become depleted, species adopt slow strategies, also known as K selection, where K represents the carrying capacity of the environment. Slow LH strategies trade fast development and mating for slow development and parenting; they raise few, high-quality offspring who can compete for and monopolize the depleting resources of their environment (Pianka 1970). The K -slow strategy is particularly relevant to humans who rely on skills and knowledge to monopolize resources in contest competition, where resources are unevenly distributed to K strategists; this is in contrast to scramble competition, where resources are evenly distributed, leading to fast LH strategies (Rogers 1992). Cross-cultural data on preindustrial societies suggest that resource scarcity arising from high population densities and related energy limitations favor the development of slower LH strategies involving paternal presence and comparatively high biparental care of offspring (Hewlett 1992; Katz and Konner 1981).

Rushton (1985) was among the first to apply the density-dependent r – K framework to the study of human LH strategies. However, research on resource scarcity as a type of environmental harshness has not flourished partly because other factors, such as age-specific mortality and environmental unpredictability (discussed in the following section), play more important roles than resources alone in shaping LH traits (Ellis et al. 2009). Another reason is that there is no reliable measure for resource availability or scarcity at the individual level. In modern life, the putatively representative indicator of available resources is family income or socioeconomic status (SES) at the individual level and per capita income at the population level. However, SES is an inadequate indicator of the evolutionary concept of resource availability or scarcity for several reasons. It has the floor effect in that even a low SES in resource-rich, developed societies does not approach the resource depletion point below the environment's carrying capacity. It is also potentially confounded with two other LH concepts. First, in most metropolitan areas, a low SES is

associated with an environment that is high in crime and violence, which represents a separate mortality–morbidity component of environmental harshness and unpredictability. Because of this potentially confounding measurement, low rather than high SES has been shown to be associated with fast LH strategies (e.g., Belsky et al. 1991) against LH predictions. Second, it is potentially confounded with intraspecific competition, with higher SESs representing success in intraspecific competition. The opposite effects of competitiveness and resource abundance on LH strategies nullify the potential effect of SES.

Mortality–Morbidity

Whereas resource levels seem to influence LH strategies uniformly across the lifespan, the effect of mortality–morbidity on LH is age and stage dependent (Ellis et al. 2009): “Indeed, extrinsic morbidity–mortality is not defined by the source of death or disability but rather by which members of the population are affected” (p. 219). In general, if extrinsic causes of mortality–morbidity are insensitive to the survival efforts of the able adults of a population, high frequencies of such extrinsic risks lead to fast LH strategies because natural selection favors accelerated development and reproduction before extrinsic mortality–morbidity strikes (Promislow and Harvey 1990). If such mortality–morbidity as that derived from endemic disease exposures mainly affects the young and weak of the population, natural selection tends to select slow LH strategies because LH trade-offs that favor body repair and maintenance, including immune competence over mating, should enable individuals to escape disease attacks (Ellis et al. 2009). In species where juveniles suffer from high rates of mortality–morbidity, the affected fast–slow LH strategies depend on whether mortality–morbidity responds to parental investment, as well as juvenile investment (Ellis et al. 2009). If parental investment reduces extrinsic risk for the juveniles, natural selection should favor slow LH strategies by increasing physical development to build stronger disease or predatory defense mechanisms. If mortality–morbidity is insensitive to parental investment, natural selection should favor fast LH to accelerate growth and

development to outlive the age-specific extrinsic risks.

Low levels of extrinsic mortality–morbidity, however, do not necessarily lead to slow LH strategies (Ellis et al. 2009). Under the conditions of low environmental harshness that characterize human evolution, density-dependent factors, such as resource and intraspecies competition, become more relevant determinants of LH strategies (Pianka 1970). Low mortality–morbidity combined with low resource availability and high competition should lead to slow LH strategies, whereas low extrinsic risks accompanied by high resource availability and low competition should lead to fast LH strategies. However, few human LH studies have examined resource levels or competition. Conducted primarily in the West, extant studies have examined exposure to violence, crime, and antisocial activities (Brumbach et al. 2009) and rundown neighborhood conditions (Crowder and Teachman 2004), including the presence of gangs, abandoned cars, and graffiti (Upchurch et al. 1999), as indicators or proxies of environmental harshness. These proxies generally correlate with fast LH strategies.

Environmental Unpredictability

Stochastic spatiotemporal variations in resource levels and mortality rates are defined as environmental unpredictability, which shapes fast–slow LH strategies (Ellis et al. 2009). These random fluctuations between good times and bad times are caused by such uncontrollable factors as predatory behavioral idiosyncrasy, weather change, or pathogenic breakout and disappearance. Unpredictable environmental fluctuations increase the variance and decrease the mean of fitness (Phillippi and Seger 1989). Because the geometric mean is negatively affected by the variance, reducing the variance increases the geometric mean despite it also reducing the arithmetic mean. In fluctuating environments where fitness is calculated with the geometric rather than the arithmetic mean, phenotypes with reduced variance are favored over those of higher variance and higher mean fitness (Phillippi and Seger 1989).

This trade-off between having a more variable number of offspring across time (with a higher arithmetic mean) and having a more constant number of offspring over time (with a higher geometric mean) is called “bet-hedging” (Phillipi and Seger 1989), for which there are two types: conservative and diversified bet-hedging. In conservative bet-hedging, animals reduce the variance of fitness across time and on specific occasions by decreasing the number of offspring in good times or in stable environments so that the number of offspring is closer to the mean. In diversified bet-hedging, animals reduce the fitness variance across time and space by increasing the number of offspring during bad times or in unpredictable environments. The two types of bet-hedging achieve the same end result, which is reduced variance of fitness across the lifespan or across generations (Phillipi and Seger 1989). Because conservative bet-hedging trades off offspring quantity for quality, it can be regarded as a slow LH strategy. Diversified bet-hedging, which increases offspring quantity at the cost of quality, can be considered a fast LH strategy.

According to Ellis et al. (2009), short-term environmental unpredictability (e.g., within generations) that causes variations in juvenile mortality predicts diversified bet-hedging to reduce fitness variance. Fitness variance is reduced by producing more offspring, reproducing with different partners, or extending the age schedule of reproduction, all three of which potentially diversify offspring phenotypes so that some offspring may survive environmental adversity. When variations in juvenile mortality are due to long-term environmental fluctuations across generations, natural selection favors conservative bet-hedging. Fitness variance is reduced by reducing the quantity and improving the quality of offspring so that, despite the overall number of offspring being lower than what would be optimal in good times or stable environments, the improved quality promotes offspring survival across the range of environmental fluctuations from good times to bad times. When environmental unpredictability affects adult mortality and morbidity, natural selection favors fast LH strategies: “Both high absolute levels of adult mortality

(harshness) and high variation in adult mortality (unpredictability), therefore, select for fast LH strategies” (Ellis et al. 2009, p. 229).

Central to the discussion of environmental unpredictability is the age of a population in which large variations of mortality–morbidity occur. Age-specific mortality–morbidity implies different effects or extents of an effect depending on the age or developmental stage of individuals when they experience environmental unpredictability. A robust and consistent finding from numerous human LH studies is that early childhood experiences of unpredictable environments lower the age of sexual maturation and increase the frequency of sexual activity. In such studies, early environmental unpredictability was represented by microenvironmental proxies from the childhood or early childhood environment. These include family SES (e.g., Belsky et al. 1991), residential mobility (e.g., Crowder and Teachman 2004), family and parental change (e.g., Belsky et al. 2010), disruptive and coercive family relationships (Byrd-Craven et al. 2007), maternal history of psychopathology (e.g., Ellis and Garber 2000), divorce (Mendle et al. 2006), paternal absence (e.g., Belsky et al. 1991), stepfather presence (Ellis and Garber 2000) and the presence of stranger males in the family (Ellis et al. 2003).

The results support the LH prediction that these indicators of environmental unpredictability are either directly or indirectly related to fast LH characteristics such as early menarche (e.g., Belsky et al. 1991), early commencement of sexual activity (e.g., Byrd-Craven et al. 2007), high frequency of sexual activity (e.g., Belsky et al. 2010), teen pregnancy (e.g., Ellis et al. 2003), sexual risk taking (Belsky et al. 2010), and early age at first birth (Nettle et al. 2011). The effect of paternal absence on menarche seems to be most evident when fathers leave their daughters before the age of 7 years (Belsky et al. 1991; Ellis et al. 2003). For example, women whose parents separated before they were 6 years old were shown to mature earlier than girls whose parents did not separate (Quinlan 2003), and exposure to family conflicts assessed when the daughters were 7 years old was

shown to correlate negatively with self-reported menarcheal age (Moffitt et al. 1992). The effect also seems to be quantitatively accumulating, as indicated by several studies that have found that both the length of paternal absence and the amount of time that girls are exposed to unrelated adult males at home correlate with the timing of menarche (e.g., Moffitt et al. 1992).

Moreover, childhood experiences of both environmental harshness and unpredictability have the LH-predicted lasting effect on adult behavior. Self-reports of early childhood experiences of environmental harshness and unpredictability were shown to be related to the anxious style of attachment (Barbaro and Shackelford 2016), which, compared with the secure style of attachment, represents a fast LH strategy. A study across neighborhoods in England showed that adult women who grew up in low-SES neighborhoods gave birth to their first child much earlier than women who grew up in high-SES neighborhoods (Nettle et al. 2011). The same finding was reported in an earlier study (Wilson and Daly 1997); women who grew up in neighborhoods where life expectancies were shorter (as a result of extrinsic risks such as homicide) were shown to give birth at a younger median age than those who grew up in neighborhoods where life expectancies were longer.

In numerous studies on adult populations, experimentally induced mortality–morbidity has not been shown to have the intended main effect, but interacted with childhood harshness and unpredictability in predicting LH strategic outcomes. In such studies, participants have been asked about their childhood SES and then experimentally primed with stimuli suggesting threats of mortality–morbidity (e.g., news stories about rising homicide rates and future uncertainty). Among people reporting low-SES childhoods, induced mortality was associated with the desire to reproduce early and have more children, even at the cost of delaying one's education and career development; by contrast, these fast LH effects were shown to be absent in people who reported having grown up under favorable resource conditions (Griskevicius et al. 2011). Induced mortality

threats have also prompted participants with low-SES childhoods to opt for diversified bet-hedging by choosing different and riskier stocks over safer and less diversified options (White et al. 2013). Participants with low-SES childhoods have responded to induced environmental harshness with lowered resistance to temptation, high impulsivity, increased risk-taking, and shorter time orientation (e.g., spending more now and saving less for the future), whereas no priming effect has been observed for participants with high-SES childhoods (Griskevicius et al. 2013; Hill et al. 2014). Perceptions of personal control mitigate the psychological effects of resource scarcity threats only for people reporting high-SES childhoods (Mittal and Griskevicius 2014; Griskevicius et al. 2013). Collectively, this stream of research underscores the importance of early life experience in affecting human LH strategic changes.

Conclusion

Thus, the struggle for existence that Darwin described 150 years ago is currently understood to be powered by strategic allocations of the limited energy budget through LH trade-offs. Environmental cues keep active the contingent response between the interindividual struggle for existence and the intraindividual LH trade-offs. If there were unlimited resources and no obstacles to acquiring them, there would be no struggle for existence or need for the corresponding strategic LH trade-offs. Therefore, environmental cues relevant to LH trade-offs are all negative. They are referred to as environmental risks, which are further divided into environmental harshness and environmental unpredictability. Harshness refers to any physical or psychological strain on an individual organism. Possible contributors include resource scarcity, predatory risk, pathogens and disease, natural disasters, and interspecies violence – all of which are independent of an individual's effort for survival and cause mortality and morbidity. Among the elements of environmental harshness, probably most relevant to the survival of most nonhuman animals are levels of

resources and predation, which can also be inter-related because one individual's food may be another's predation. Because humans are the highest predators who have long had no rivals other than themselves, resources and intraspecific competition to monopolize resources – both of which are density dependent – become the major strain on survival and cause the struggle for existence. For both human and nonhuman animals, density-dependent resource limitations and intraspecific competition drive slow LH strategies by which individuals invest in growth and development and in their children's growth and development so that they become capable competitors for the limited resources. Other harshness elements causing extrinsic mortality–morbidity lead to fast LH strategies because fitness is more efficiently attained in a harsh environment by accelerating development and moving to early reproduction before extrinsic mortality or morbidity strikes.

Published studies based on human populations generally support this theorizing about the role of environmental harshness in regulating human LH trade-off strategies. However, extant human LH studies have generally not pursued a density-dependent approach (Ellis et al. 2009), nor have they examined intraspecific competition, particularly in predicting human LH strategies. The ever-increasing and complex social groups of human evolution render most selection pressures density dependent. Resource scarcity and abundance are density dependent, as are mortality and morbidity arising from such extrinsic risks as diseases, intraspecific violence, and even natural disasters; the effects of all of these factors can be converted into winning versus losing in intraspecific competition. Competition that involves garnering resources and avoiding mortality–morbidity risks therefore captures both spectra of the harshness dimension of the environment.

Humans had in some unique fashion become so ecologically dominant that they in effect became their own principal hostile force of nature [and] nothing would select more potently... than a within-species co-evolutionary arms race in which success depended on effectiveness in social competition. (Alexander 1990, pp. 4–7)

One direction for future research is to operationalize and investigate intraspecific competition at both the individual and population levels to determine how it affects LH strategies directly and mediates the relations between environmental harshness and individuals' behaviors and LH strategies.

Whereas environmental harshness refers to the absolute levels of morbidity and mortality, environmental unpredictability refers to the random or stochastic variations of morbidity and mortality. Stochastic variations rather than high frequencies of extrinsic risks are probably more relevant to human evolution because it presents a more formidable task in mastering these two hostile forces of nature. LH theory distinguishes between adult and juvenile populations that will be affected by unpredictable mortality and morbidity. When the adult population is the target of unpredictable mortality–morbidity, species adopt a fast LH strategy to allocate energy and resources for fast development and reproduction if there is adequate bioenergy, as determined by the harshness dimension of environmental risk. When juveniles are the target of mortality, species respond either with conservative bet-hedging (a type of slow LH strategy) or diversified bet-hedging (a type of fast LH strategy), depending on whether juvenile mortality and morbidity respond to parental investment. Published human LH studies do not distinguish between these two types of population mortality because they are highly correlated (Ellis et al. 2009) and because, with high parenting and child care, the child–adult mortality differential never reaches a scale such as those of many other animals (e.g., turtles) that require different LH strategies to respond to high juvenile mortality. However, it is also shown that childhood experiences of both harshness and unpredictability have a lasting effect on adult LH strategies, whereas – at least for some experimental studies – induced harshness and unpredictability of adulthood do not have the expected main effect on behavior. These findings suggest the need for further considerations when applying LH theory to humans as a species-general theoretical framework.

One consideration is the distinction between uncontrollability and unpredictability (Brumbach et al. 2009). Uncontrollability refers to the complete separation between an event's happening and an individual's effort to influence the event, whereas unpredictability includes the additional inability to anticipate and avoid the event. Because LH theory is species general, many mortality and morbidity risks that are defined as unpredictable for animals in general may be uncontrollable but predictable for humans because of the large human brain. The fact that hominin populations (e.g., *Homo erectus*) migrated from Africa as early as 2 million years ago to populate the rest of the world suggests that at least some of the uncontrollable events driving intensive human evolution in the Pleistocene must often have been predictable, because the primary reasons for migration are to purposefully seek resources and avoid risks. In fact, famine, disease, and intraspecific conflict and violence, which are all defined as unpredictable by LH theory, may be uncontrollable but predictable because ancestral humans can anticipate their coming and make adjustments to avoid them; this includes migrating from Africa multiple times during human evolution. The evolution of the large human brain, which is itself a slow LH trait, results from environmental variations (e.g., glacial and interglacial temperature variations had a greater role than the mean cooling of the ice age in effecting brain enlargement; Ash and Gallup 2007) that are certainly uncontrollable but may be predictable because they would otherwise not have led to the large human brain as a slow LH trait. It is therefore possible that many of the environmental unpredictabilities defined by LH theory are predictable to humans who respond not with fast but with slow LH trade-off strategies or with a mixture of both. An apt example of a mixture of the two strategies is the human practice of weaning offspring early and shortening interbirth intervals (fast strategies), which are accompanied by feeding offspring with prepared foods and extensive child care by kin through alloparenting and siblings helping at the nest (slow strategies). Future human LH studies can

hypothesize mixed LH strategies, especially in response to uncontrollable but predictable environmental risks.

Synonyms

Stochastic environment; Unpredictable environment

Definition

Uncertainty about future environmental outcomes.

Introduction

Choosing to stay at a party rather than leave depends on which people might still show up. Buying a house depends on future employment prospects. In making decisions, the best course of action often depends not only on current conditions but also on predictions about the future (Frankenhuis et al. 2016b).

Environments might be predictable for two reasons. First, environmental states might be autocorrelated across time (Nettle et al. 2013). If it rains today, it is likely to rain tomorrow. Second, even without such autocorrelation, *other* current cues might predict future conditions. For example, female parasitic wasps lay more eggs on low-quality hosts if conditions indicate an approaching thunderstorm (dropping barometric pressure) than if conditions indicate a fair summer day (steady barometric pressure). Thunderstorms might kill them, so rather than saving their eggs for a higher-quality host, the wasps deposit their eggs immediately (Roitberg et al. 1993).

Adaptation to Environmental Unpredictability

Natural selection favors different adaptations, depending on the degree of environmental

predictability (Ellis et al. 2009; Frankenhuis et al. 2016a). If an environment is stable (and therefore predictable) generation after generation, natural selection might favor reliably developing phenotypes that are specialized for the prevailing conditions. If an environment is stable (and predictable) within a lifetime, but varies across lifetimes, natural selection might favor developmental plasticity – the ability to adjust development based on experience – if experience provides cues to the environmental state (Frankenhuis et al. 2013b). If an environment is variable across lifetimes and organisms cannot infer its state within lifetimes, natural selection might favor strategies that avoid extreme payoffs – either by producing generalist phenotypes, which do moderately well in all environmental conditions, or mixtures of specialists, each of which does very well in a subset of environmental conditions (Frankenhuis et al. 2016a).

Some evolutionary psychologists hypothesize that over the course of human evolution, the degree of environmental unpredictability might itself have been stable (and predictable) within a lifetime but variable across lifetimes (Ellis et al. 2009). If so, natural selection might have favored developmental plasticity for dealing with environmental unpredictability: organisms that infer the degree of environmental unpredictability during ontogeny and adapt accordingly (Frankenhuis et al. 2013a). Consistent with this idea, exposure to unpredictable childhood environments is associated with “fast” life histories, such as earlier age of first sex and first conception, higher rates of aggressive and delinquent behavior, and reduced health (Belsky et al. 2012; Brumbach et al. 2009; Nettle et al. 2011; Simpson et al. 2012). These associations remain after controlling for exposure to harshness, i.e., mean levels of morbidity and mortality.

Evolutionary developmental studies typically measure environmental unpredictability as residential changes, family disruptions, and parental job changes. An open and interesting question for future research remains whether these measures truly capture environmental unpredictability or different components of harshness (Nettle et al. 2012). A second challenge will be to empirically assess the idea that over the course of

human evolution, the degree of environmental unpredictability was itself stable (and predictable) within a lifetime but variable across lifetimes (Nettle et al. 2013). A third challenge will be to determine how individuals might infer the degree of environmental unpredictability based on their experiences (Frankenhuis et al. 2013a).

Conclusion

In *Roadhouse Blues*, Jim Morrison sings: “The future’s uncertain, and the end is always near” (The Doors, 1970). This sentence is contradictory. If the end is always near, then the future is certain: imminent death. The future is uncertain when it is not possible to predict it, that is, when current conditions are uncorrelated with future outcomes and there are no cues that predict future outcomes (Nettle et al. 2013).

Definition

Environmental unpredictability is characterized by nondeterministic and variable amounts of change within a temporal environment (Botero et al. 2015; Philippi and Seger 1989). When exposed to greater environmental unpredictability, organisms favor *bet-hedging* to maximize their fitness (Botero et al. 2015). Bet-hedging involves overall reduced variance in progeny yields, manifesting in decreased fitness in typical conditions in exchange for increased fitness in unpredictable conditions (Philippi and Seger 1989; Simons 2011; Slatkin 1974). Bet-hedging operates on the assumption that some reproductive success is better than no reproductive success in certain years (Philippi and Seger 1989).

Introduction

In unpredictable environments, organisms are unable to make reasonable predictions about future environmental occurrences. Unpredictability spurs organisms to engage in risk-management based on the duration of unpredictability and its impact on mortality-morbidity. Bet-hedging strategies are only favored when environmental unpredictability produces variance in *juvenile* survivorship (Ellis et al. 2009). By contrast, when environmental unpredictability impacts variance in *adult* morbidity-mortality rates, evolution (over time) favors accelerated reproduction and overall faster life history strategies rather than diversified bet-hedging (Ellis et al. 2009). Consequently, bet-hedging strategies are favored when unpredictable environments impact juvenile survivorship but may not be favored when unpredictable environments impact adult mortality.

Bet-Hedging as Risk Management

Different forms of bet-hedging represent distinct forms of risk management in response to varying environmental conditions; there is no single “optimal” form of bet-hedging. As a consequence, environmental unpredictability forces organisms

to evaluate different risk management strategies in order to limit their potential fitness losses (Ellis et al. 2009). Bet-hedging requires organisms to make trade-offs. Organisms are required to make sacrifices to either their number of offspring or variance in offspring quality relative to others (Starrfelt and Kokko 2012). Conservative and diversified bet-hedging are two possible strategies for managing risks in unpredictable environments.

Conservative bet-hedging (“play it safe”) occurs when organisms produce fewer, relatively higher quality offspring that are better equipped to deal with average environmental conditions (e.g., producing a clutch of eggs, all of intermediate size; Botero et al. 2015; Ellis et al. 2009; White et al. 2013). Conservative bet-hedging tends to contribute to the development of relatively slow life history strategies, as individuals delay reproduction to amass resources and invest more in their offspring’s survival (Ellis et al. 2009). *Diversified bet-hedging* (“don’t put all your eggs in one basket”) is favored when conservative bet-hedging fails (Botero et al. 2015; Ellis et al. 2009). Diversified bet-hedging leads to the production of numerous diverse offspring, equipped to deal with multiple niche environmental conditions (e.g., producing a clutch of eggs of multiple different sizes). Unlike conservative bet-hedging, diversified bet-hedging does not always favor the adoption of slow life history strategies. Given that phenotypic diversity can be achieved through a wide range of behaviors (e.g., multiple matings, intraclutch variation, accelerated reproduction), a wide range of life histories may be employed to combat unpredictability in juvenile mortality (Ellis et al. 2009; Starrfelt and Kokko 2012).

Examples of Bet-Hedging

Bet-hedging strategies manifest across all taxa, including plants, bacteria, and animals (reviewed in Simons 2011). Plant examples of bet-hedging include diversified timing of seed germination and elevated ovule numbers per flower (reviewed in Simons 2011). The bacteria *Escherichia coli* exploits phenotypic diversity to

bet-hedge against unpredictable environmental stressors (reviewed in Ellis et al. 2009). The mammalian white safika engages in conservative bet-hedging when exposed to extreme environmental unpredictability (Dewar and Richard 2007). These examples highlight the adaptation of bet-hedging across multiple taxa under unpredictable environmental conditions (Simons 2011).

Conclusion

Bet-hedging is a risk-management strategy utilized to maximize fitness in the face of environmental unpredictability and low juvenile survivorship. Bet-hedging strategies may be *conservative* (e.g., by producing offspring all of one size) or *diversified* (e.g., by producing offspring of multiple different sizes). Bet-hedging of both types have been demonstrated across taxa in response to unpredictable environmental conditions.

Epinephrine

Sujita Kumar Kar and Sumit Modi
Department of Psychiatry,
King George's Medical University,
Lucknow, UP, India

Synonyms

Adrenaline

Definition

It is a sympathomimetic agent.

Introduction

The autonomic nervous system has been divided into the sympathetic arm and parasympathetic arm. The sympathetic arm delivers its action by releasing the neurochemicals – epinephrine and norepinephrine – whereas the parasympathetic arm delivers its action through release of acetylcholine. Epinephrine is a key sympathomimetic agent, commonly known as adrenaline. In the literature the terms “epinephrine” and “adrenaline” are interchangeably used. It is secreted from the adrenal medulla. It is often released in response to stress and determines the bodily responses to stress. It is also known as the “fight or flight hormone” (Goldstein 2010). Certain situations or events are recognized as threatful for the homeostasis of the body and are capable of stimulating the adrenal medulla to release epinephrine. For example, exposure to cold environment, emotional stress, severe painful conditions, and hypoglycemia induced by insulin activate the adrenal medulla to secrete epinephrine (Goldstein 2010). Certain evidences exist that demand of work is also capable of increasing the release of epinephrine among men (Pollard et al. 1996). It is possible that job pressure and perceived stress due to demands at the workplace might be responsible for release of stress hormones.

History of Epinephrine

John Abel, the scientist from the United States, prepared a crude extract from the adrenal gland and named it “epinephrine” in 1857. Then, in 1901 Jokichi Takamine prepared the pure form from the extract and patented it.

The Japanese scientist Jokichi Takamine first isolated the substance with technical help from Keizo Uenaka (Saito and Kamiyama 2011). Henry Dale, a research scientist in the United Kingdom, named it “adrenalin” as it was a different form of extract (pure form), to which John Abel used the name “epinephrine” (Aronson 2000). Epinephrine is chemically known as dihydroxyphenylmethylaminoethanol [i.e., (R)-1-(3,4-dihydroxyphenyl)-2-methylaminoethanol]. It is the name issued by the International Union of Pure and Applied Chemistry (IUPAC). Various countries adopted different generic names for epinephrine. The British approved name is “adrenaline,” whereas the internationally approved name is “epinephrine.” In Australia, France, Scandinavian countries, and many Asian and African countries, it is known by the name “adrenaline” (Aronson 2000). Epinephrine has been marked by various brand (proprietary) names in various countries (e.g., epipen in Britain).

Biochemistry and Physiology of Epinephrine

Epinephrine is a catecholamine. It has resemblance with other catecholamines like dopamine, epinephrine, and norepinephrine (Kamal and Lappin 2019). Epinephrine along with norepinephrine gets synthesized in the adrenal medulla or in the neurons of the sympathetic nervous system (Kamal and Lappin 2019). All the catecholamines including epinephrine have the same precursor amino acid (i.e., tyrosine). Tyrosine undergoes hydroxylation followed by decarboxylation in a sequential manner to form dopamine, which later undergoes hydroxylation to form norepinephrine. Norepinephrine then undergoes

methylation to form epinephrine. Dopamine, norepinephrine, and epinephrine are all active forms and together known as catecholamines (Paravati and Warrington 2019). Degradation of epinephrine occurs by several rate-limiting enzymes like monoamine oxidase (MAO) and catechol-O-methyl transferase (COMT). The end product of metabolism of epinephrine and norepinephrine is vanillylmandelic acid (VMA) (Kamal and Lappin 2019).

The release of epinephrine is regulated via the activation of hypothalamo-pituitary-adrenal axis (Goldstein 2010). The regulation of epinephrine release happens through feedback control. Hypothalamus releases adrenocorticotrophic-releasing hormone (ACTRH), which stimulates the anterior pituitary to release adrenocorticotrophic hormone (ACTH), which further acts on the adrenal medulla to cause release of epinephrine. To maintain the homeostasis in the body, through negative feedback mechanism, release of ACTH and ACTRH is controlled (Goldstein 2010).

Epinephrine, being a sympathomimetic agent, causes activation of the alpha 1 receptors in the smooth muscles of the blood vessels producing vasoconstriction, as a result of which there is increase in blood pressure (diastolic), cerebral perfusion pressure, and coronary perfusion pressure (Gough and Nolan 2018). It also produces pupillary dilatation and piloerection through its action on the alpha 1 receptor.

Epinephrine also acts on the receptors located in myocardium, skeletal muscles, and smooth muscles of the bronchial tree of the lungs. Epinephrine along with norepinephrine causes tachycardia, bronchodilation (through beta 2 receptor), increased contractility of the heart (through beta 1 receptor), and hyperglycemia (through alpha 2 receptor) (Kamal and Lappin 2019; Paravati and Warrington 2019). Epinephrine mediated glycogenolysis, and lipolysis mediated through the beta 2 and beta 3 receptors, respectively. Increase glucagon secretion and decreased insulin secretion are also mediated by epinephrine through beta 2 and alpha 2 receptors, respectively (Paravati and Warrington 2019).

Evolutionary Significance of Epinephrine

The adrenal medulla develops from the neuroectoderm. In stress-free states, the level of secretion of epinephrine almost ceases, whereas during severe stressful situation, the secretion of epinephrine reaches the peak (Pohorecky and Wurtman 1971). In the lower vertebrates, the cytoarchitecture of the adrenal is different from that of higher vertebrates. As there is progression from lower to higher vertebrates, the intimate association between the adrenal cortical cells and adrenal medullary cells (chromaffin cells) increases (Pohorecky and Wurtman 1971). Among amphibians, the adrenal tissue is present within the mesonephros (equivalent to mammalian kidney), and the chromaffin cells are present within the steroid-producing cells in a close association (Pohorecky and Wurtman 1971). The distribution of chromaffin cells in reptiles follows a unique pattern. The norepinephrine-producing chromaffin cells are present on the surface of the adrenal gland in the form of a band (extra-glandular in location), whereas predominantly epinephrine-producing chromaffin cells are present within the adrenal gland (intraglandular in location). Among birds, the chromaffin cells are randomly scattered in the adrenal gland, whereas among mammals, they are clustered in the center of adrenal gland (Pohorecky and Wurtman 1971).

Epinephrine and Health Significance

Catecholamines like epinephrine serve various physiological functions in the body. Their excess or deficit is likely to cause mental as well as physical disorders (Kamal and Lappin 2019). Tumors of the adrenal medulla (pheochromocytoma) and sympathetic ganglia (paraganglioma) may result in excessive production of catecholamines like epinephrine and norepinephrine, which is often clinically manifested as headache, hypertension, and tachycardia (Berends et al. 2019; Kamal and Lappin

2019). Increases urinary level of vanillylmandelic acid (VMA) and homovanillylmandelic acid (HMA) are sensitive biomarkers of pheochromocytoma and paraganglioma (Berends et al. 2019; Kamal and Lappin 2019).

Evidences support that stress induces the release of stress hormones, which prepare the body to readjust its needs during stress. Acute severe stress prepares the body for a flight or fight response, during which there occurs reconfiguration of the immune system. Transient decline in the immune system during acute severe stress increases the vulnerability for diseases (Adamo 2014). Stress hormones including epinephrine help in consolidation of memory that is emotionally aroused. The interaction between amygdala and hippocampus mediates the process of consolidation of memory (McIntyre and Roozendaal 2007). However, as epinephrine is incapable of crossing the blood-brain barrier, there must be some complex mechanism operating peripherally that facilitates the central processing of memory (McIntyre and Roozendaal 2007).

Lower norepinephrine to epinephrine ratio in the urine is indicator of high suicidal behavior (Ostroff et al. 1985). Epinephrine and norepinephrine are involved in the pathogenesis of mood disorders, stress-related disorders, anxiety disorders, and attention-deficit hyperkinetic disorder (Berends et al. 2019). The pharmacological agents used for treatment of these disorders alter the activity on epinephrine and norepinephrine. Certain addictive substances (stimulants) like amphetamine and cocaine act in the body by increasing the level of epinephrine. Persons using the stimulants and the sports persons, who use performance enhancers (certain kinds of stimulants and anabolic steroids), often experience adrenaline rush in the body (Davis et al. 2008).

Epinephrine (adrenaline) has been used in the anaesthetic, critical care, as well as pain management settings (Saito and Kamiyama 2011). Epinephrine has been used for cardiopulmonary resuscitation. It is a life-saving drug, though there are some evidences that it compromises the microcirculatory flow of blood to the brain (Gough and Nolan 2018). Epinephrine has been

used as a life-saving treatment modality in management of anaphylaxis (Sicherer et al. 2017). It has been reported that the cerebrospinal fluid catecholamine levels are elevated in patients with subarachnoid hemorrhage with high level of disability and who experience early mortality. Epinephrine can be considered as a sensitive marker of such outcomes associated with subarachnoid hemorrhage (Moussouttas et al. 2012). During certain surgical procedures, topical epinephrine has been used for hemostasis due to its profound vasoconstricting property (Korkmaz et al. 2015).

Conclusion

Epinephrine has a pivotal role in maintaining the homeostasis of the body. It enables the individual to combat threats and stress. It has significant implications in physical as well as mental health. It has been used as a life-saving measure in cardiorespiratory arrest and severe allergic conditions.

Episodic and Semantic Counteraction

► Scope Hypothesis, The

Episodic Memory

Victoria L. Templer

Providence College, Providence, RI, USA

Synonyms

Autobiographical memory; Declarative memory; Episodic-like memory; Explicit memory

Definition

Memory of personal past events, including the what, where, and when aspects of the event that can be explicitly accessed. In addition to these content-based aspects of a remembered experience, information about the event is integrated in a single representation and can be flexibly used to support adaptive behavior.

Introduction

When Endel Tulving distinguished episodic memory (EM from here on) from semantic memory (Tulving 1972), a crucial framework for psychological studies on EM was established. Semantic memory, or knowledge or facts about the world, is unlike EM because it does not include experiential properties or sensory information related to the occasion on which information was learned. Semantic memory, like the fact that Boston is the state capital of Massachusetts, is unlinked to the occasion on which this piece of information was learned. Such facts that are simply *known* to be true are conceptually organized rather than temporally organized in experiences like they are in EM. This distinction has propelled

studies of not only human but of nonhuman animal (nonhumans from here on) EM. We know that humans have EM because they can verbally report a memory from the past, like the memory of a last Thanksgiving holiday. Determining if nonverbal species have EM presents an obvious challenge, but comparative memory researchers are constantly developing experimental paradigms to overcome this hurdle. Though the presence of EM in nonhumans is controversial, most comparative and evolutionary psychologists contend that EM has a long evolutionary history. Cognitive and neurobiological studies that examine the presence of EM features in nonhumans are crucial in understanding the mechanisms underlying EM and in charting potential time points at which these remarkable mnemonic abilities emerged.

Human EM

Mental time travel allows humans to “go back in time” when retrieving the memory of a recent birthday: where and when the celebration took place, how good the food was, and whose company was enjoyed. EM allows a vivid picture of how the elements that comprised a personal past event unfolded over time to be painted. In addition to being contextually rich, EMs are also personally relevant. In particularly meaningful or self-defining recollections, EMs are ripe with emotion and “the feeling of being there.” This experiential ability to mentally place oneself in the past is called *autonoetic consciousness*. Human EM is similar, but should be distinguished from autobiographical memory. *Autobiographical memory* is a more involved phrase used to describe the self-memory system that combines salient EMs from one’s life with semantic memories. Together, these episodic and semantic memories feed the working self, which includes goals and images of the self.

Human introspection, recollection, and even the working self in the case of autobiographical memory have served as tools that have permitted a definition of human EM to be constructed. While

autonoetic consciousness and associated phenomenology may offer a rich lens with which humans can view their own EMs, both rely on verbal reports of subjective mental experience. For this reason most evolutionary-oriented researchers argue that phenomenological experience is not a necessary ingredient of EM. Indeed, natural selection did not select for the feelings that accompany episodic recollection, but rather the *functions* these memories served in survival and propagation of the species over time. After all, the principle of parsimony is useful because it mirrors what is found in nature. Conceptually minimalistic definitions that focus on *how* information is stored and retrieved, like the time and place of the experience, as outlined in Tulving’s original definition (Tulving 1972), offer objective functional criteria that have recently been applied to studies of EM in humans.

EM in Nonhumans

Despite the anthropocentric definition of EM that requires conscious experience and is therefore unique to humans, this view has been challenged by combining content-based approaches with paradigms that are testable in nonverbal species (for reviews, see Allen and Fortin 2013; Eichenbaum 2013; Templer and Hampton 2013b).

The first study that applied functional objective criteria for EM to nonhumans was Clayton and Dickinson’s (1998) demonstration that food-caching scrub jays could remember what types of food they stored where and when (WWW memory). To circumvent the issue that some reformulations of EM since Tulving’s original definition stress the importance of autonoetic consciousness and knowledge of the subjective self through time, this demonstration was dubbed “episodic-like memory.” Analogous WWW paradigms have been developed in several species, including magpies, black-capped chickadees, honeybees, rhesus monkeys, rats, mice, meadow voles, pigs, and humans. Studies have indicated that many of these species are capable of at least

the “what” and “where” aspects of EM and some are capable of all three, depending on the experimental paradigm (for reviews that discuss these studies, see Templer and Hampton 2013b).

Species Differences in “When”

The “when” aspect of WWW is arguably the most challenging element of EM to demonstrate. Questions of what is mentally represented when animals make apparent “when” judgments in WWW paradigms have been raised. For example, an initial concern of the Babb and Crystal (2005) study was if rats might have used time of day at testing rather than “when” or absolute (clock) time. This was controlled for in later studies by both Crystal and Roberts’ groups, but Roberts took this idea of testing for the temporal basis of EM further in an elegantly controlled design which showed that rats remember “how long ago” rather than absolute time (Roberts et al. 2008). This result is not surprising given that natural foraging decisions in rats depend on elapsed time and that the ecological relevance of a rat knowing absolute time is equivocal. In a similar vein, honeybees were shown to use circadian timing rather than “when” in a WWW memory test, likely because nectar availability follows a strict circadian pattern (Pahl et al. 2007). Species-specific ecological relevance also likely explains why monkeys failed to remember when preferred food became rotten as compared to when less preferred food remained fresh in Hampton’s adaptation of the scrub jay food-caching paradigm: monkeys do not naturally cache and keep track of decay rates of perishable and nonperishable food (Hampton et al. 2005).

To further dissociate the cognitive mechanism underlying temporal judgments in monkeys, Templer and Hampton (2013a) showed that order of events is not distinguished based on memory trace strength (familiarity), ordinal position of items, or amount of time passed, but is instead based on number of intervening items that occurred. Clearly, different species encode when, or temporal order, differently and discovery of these differences is not only interesting but crucial as they critically inform functional

characterizations of EM. Progress is made when cognitive behavioral experiments dissociate these more nuanced information processing mechanisms that underlie aspects of EM. It is also important to note that the use of one cognitive mechanism, such as when in absolute time, is not necessarily more sophisticated or evolved than a strategy that relies on “how long ago.”

Recollection Versus Familiarity

Episodic recollection of past experiences is distinguished from a sense of familiarity for stimuli previously presented. Receiver operating characteristic (ROC) is a powerful method of signal detection analysis used to quantify contributions of recollection and familiarity in a recognition memory task. Rats have been shown to have a dual processing system for recognition: their response patterns mirror humans in the indication of a familiarity process as well as a separate recollective process. It has also been shown that the hippocampus is critical in the threshold retrieval characteristic of recollection but is not necessary for familiarity judgments. Corroborating this evidence of hippocampal involvement in EM processes but not familiarity, the Eichenbaum group has also shown that the hippocampus is critical for distinguishing the order of odors of rats sampled but not for familiarity-based recognition of those odors alone (see Eichenbaum 2013 and Allen and Fortin 2013 for a review of these studies).

Neurobiological Studies Inform the Integrative Nature of EM

A requirement of EM is that it is integrative. Neurobiological studies offer a useful approach to this structural component of EM as the brain is a system that integrates sensory information into episodes. What defines an episode might be different for different species, but the neural structures, namely, the hippocampus and adjacent cortical structures in the parahippocampal regions, are highly conserved across species. Neurobiological studies in rodents and monkeys have

mapped how these streams of information about “what” and “where” are processed and integrated as item-place associations in the hippocampus. Before reaching the hippocampus, parallel processing occurs in two general streams. Item information, or “what,” is processed by the perirhinal cortex and lateral entorhinal cortex, and context, or “where,” information is processed by the postrhinal cortex (parahippocampal in primates) and medial entorhinal cortex. Neural pathways for the processing of “when” information are more challenging (Allen and Fortin 2013), but cells that keep track of time, known as “time cells,” have been identified in the hippocampus (Eichenbaum 2013). Additional evidence in human functional magnetic resonance imaging and rodent single-unit recordings and lesion studies indicate that the hippocampus is responsible for the temporal organization of mnemonic representations.

Future Directions and the Combination of Cognitive Behavioral and Neurobiological Approaches

The neurobiological studies described here are crucially informative, but researchers have importantly pointed out that memory types should not be determined solely on the basis of brain structures involved rather than cognitive mechanisms (Eichenbaum 2013; Templer and Hampton 2013b). The functional aspect of EM is ultimately behavioral. It has become increasingly apparent that the most informative studies combine innovative behavioral paradigms that identify *what* information is mentally represented with neurobiological manipulations that identify *how* information is mentally represented at the neural level. Cognitive and neurobiological methodologies have converged in several elegant studies (e.g., see Allen and Fortin 2013; Eichenbaum 2013; and Templer and Hampton 2013b for several examples). Yet, many researchers primarily operate as either neurobiologists or cognitive behaviorists, rather than cognitive neuroscientists. Application of newly developed and sophisticated behavioral techniques

to cutting-edge neurobiological investigations, including methods such as optogenetics, is integral to future success in the EM field. Such behavioral tasks that capture EM’s functional properties include its flexibility, accessibility or metacognitive properties, future-oriented and planning capabilities, and source memory components.

Conclusion

Evolutionary-based approaches have provided a wealth of knowledge about underlying information processing systems involved in encoding and retrieving an event. As such, both theoretical characterizations of EM and functional characterizations of the hippocampal system have benefited greatly. Significant progress has been made when researchers (1) move away from anthropocentric definitions of EM, (2) combine cognitive behavioral approaches with neurobiological methodologies, and (3) ask what features of EM are shared and not shared by humans and nonhumans rather than asking the unsophisticated question of “do animals have EM.”

Erasmus Darwin

Luis Córdón
Eastern Connecticut State University,
Willimantic, CT, USA

Introduction

Charles Darwin, though he produced the most coherent and influential account of the evolution of species, was not the first Darwin to publish on the subject: That honor belongs to his paternal grandfather, Erasmus Darwin. A true polymath, Erasmus Darwin was a physician, poet, and inventor and so renowned in his time that he was offered the position of personal physician to the King, a post which he refused, preferring to continue treating the relatively poor country folk instead. Having studied at St. John's College, Cambridge, as well as in Edinburgh, he practiced as a physician first in Nottingham and then in Litchfield, where he established himself as a prominent figure in the local scientific community.

In addition to his work as a physician, he cultivated a great interest in taxonomy and botany, maintaining a large botanical garden, and building enough of a reputation that he was very close to accompanying Captain James Cook as a naturalist on one of his voyages (prefiguring in a

remarkable way the path his grandson would eventually follow), but he was prevented from doing so by conservative pressures in the scientific establishment of the time. Such pressure was applied in response to Darwin's unfortunate penchant for sharing his free-thinking, very liberal opinions quite openly and freely. He was an outspoken advocate for equality between the sexes, including education for women, as well as a vocal opponent of slavery. Additionally, he openly rejected conventional contemporary Christian views on both creation and homosexuality, refusing to pass judgment on his numerous homosexual friends as England became less tolerant of them.

Science

Although he was a Fellow of the Royal Society, Darwin was also a very active member and promoter of the Lunar Society, an early scientific society based in the English Midlands, providing a country alternative to the London-based Royal Society. The group's name derived from their custom of meeting each month on the occasion of the full moon, which provided sufficient light for the members to safely return home after the meeting in those days before the advent of streetlights. His circle of friends and associates was a truly remarkable group, including James Watt, inventor of the steam engine; Josiah Wedgwood, the famed potter; discoverer of oxygen Joseph Priestley; William Withering, the physician who introduced digitalis into medical practice; and even Benjamin Franklin, who introduced Darwin to the wonders of experimenting with electricity.

Darwin had a great fascination with machinery and was thoroughly convinced that the widespread use of machines in industry and manufacturing would be a great boon to humanity bringing about an industrial golden age that would improve life for all. He put this interest into action with a remarkable range of inventions, the best-known of which was a "speaking machine," the partially-completed prototype of which fooled some people, hearing it for the first time, into thinking they had heard a real

person speaking. The prototype's vocabulary was limited to saying "papa" or "mama," but that it worked at all is testament to Darwin's genius. He also designed one of the first mechanical copying machines, as well as a steam-powered vehicle which he called a "fiery chariot," and his design for a carriage steering system was later used in early automobiles.

Poetry

Beyond science and mechanics, Darwin's other great love was poetry, and poems were his main means of expression of his ideas, including political, historical, and scientific thoughts. His first poetic success was *The Loves of the Plants* (1789), in which he presented the current scientific understanding of plant reproduction in frankly sexual, even erotic, images. In another example of his rather radical leanings, he soon after published a revised edition incorporating new verses about the wonders of cannabis. Though the prurient portrayals of plant sexuality were the main draw, the poem also extends its metaphor to include an open, very blunt condemnation of slavery, in a series of verses noting that as newly discovered delicacies such as cashews made their way eastward across the Atlantic, a similarly valuable human cargo was shipped to the West:

E'en now, e'en now, on yonder Western shores
Weeps pale Despair, and writhing Anguish
roars:
E'en now in Afric's groves with hideous yell
Fierce SLAVERY stalks, and slips the dogs of
hell. . .

Hear him, ye Senates! Hear this truth sublime,
"HE, WHO ALLOWS OPPRESSION,
SHARES THE CRIME." (1806 edition, p. 164)

His next major work, *The Economy of Vegetation*, which together with *The Loves of the Plants* forms the larger work *The Botanic Garden*, again combines his loves of botany and poetry, in an epic that sets out to do nothing less than describe history from the dawn of creation to the start of the industrial age, illustrated lavishly by William

Blake. In its first canto, “Let There Be Light,” Darwin actually seems to be presciently describing the Big Bang theory:

Astonished Chaos heard the potent word:
 Through all his realms the kindly Ether runs,
 And the mass starts into a million suns;
 Earths round each sun with quick explosions
 burst,
 And second planets issue from the first;
 Bend, as they journey with projectile force,
 In bright ellipses bend their reluctant course;
 Orbs wheel in orbs, round centres centres roll,
 And form, self-balanced, one revolving Whole.
 (1798 edition, p. 5-6)

The other cantos go on to describe the newly discovered process of photosynthesis, along with predictions of the development of both flying vehicles and submarines. The truly controversial aspect of the poem, however, was its description of the history of the natural world without any explicit inclusion of a Creator, an idea that would be stated far more explicitly in his next book, *Zoonomia, or the Laws of Organic Life*, along with his first clear suggestion of what would become one of his grandson’s cornerstone ideas: that all life has descended, over a very long period of time, from a single ancestor. In *Zoonomia*, Darwin directly addresses evolution, posing the question, “Would it be too bold to imagine, perhaps millions of ages before the commencement of the history of mankind...that all warm-blooded animals have arisen from one living filament, which the first great cause endowed with animality, with the power of acquiring new parts, attended with new propensities...delivering down those improvements by generation to its posterity, world without end?” *Zoonomia* also takes on the adaptations of organisms to the demands of their environment, using an example that is eerily prophetic of his grandson’s work in the Galápagos:

Some birds have acquired harder beaks to crack nuts, as the parrot. Others have acquired beaks adapted to break the harder seeds, as sparrows. Others for the softer seeds of flowers, or the buds of trees, as the finches. (1809, p. 396)

This same insight, based on observations of finches, would prove vital to Charles Darwin’s argument more than 50 years later.

Erasmus Darwin’s fullest presentation of evolutionary ideas, however, comes in the posthumous publication of his epic poem, *The Temple of Nature* (1802), which presents a history of life on Earth, entirely in rhyming couplets. Many evolutionary ideas appear in the following stanzas, for example:

Organic life beneath the shoreless waves
 Was born, and nursed in Ocean’s pearly caves,
 First forms minute, unseen by spheric glass,
 Move on the mud, or pierce the watery mass;
 These, as successive generations bloom,
 New powers acquire and larger limbs assume;
 Whence countless groups of vegetation spring,
 And breathing realms of fin, and feet, and wing.

Thus the tall Oak, the giant of the wood,
 Which bears Britannia’s thunders on the flood;
 The Whale, unmeasured monster of the main;
 The lordly lion, monarch of the plain;
 The eagle, soaring in the realms of air,
 Whose eye, undazzled, drinks the solar glare;
 Imperious man, who rules the bestial crowd,
 Of language, reason, and reflection proud,
 With brow erect, who scorns this earthy sod,
 And styles himself the image of his God-
 Arose from rudiments of form and sense,
 An embryo point or microscopic ens! (Lines
 295 to 314)

In these verses, Erasmus Darwin states concisely, but poetically, that all life shares a common origin, that the common origin was a microscopic organism, and that this original life form arose in the sea and later emerged onto land.

Erasmus Darwin’s Fall from Prominence

Erasmus Darwin was very bold in his presentation of both political and scientific ideas, but his timing was rather poor, unfortunately. He and his circle had taken strong, progressive stances at a time when, facing the revolutions in America and France, a conservative backlash against these liberal intellectuals was underway. In 1791, riots erupted in Birmingham following a celebration of the fall of the Bastille, during which Joseph Priestley’s house and laboratory were set on fire and destroyed. Far from becoming widely accepted, Darwin’s evolutionary poetry was viciously mocked in 1798, in an anonymous poem (eventually attributed to George Canning)

entitled “Loves of the Triangles.” This was a parody of Darwin’s “Love of the Plants” published in the *Anti-Jacobin*, a newspaper devoted to opposing the ideals of the French Revolution. The poem is one of the most bizarre pieces in the English language, incorporating somewhat erotic verses regarding geometric forms, the story of Cinderella retold in the style of *The Economy of Vegetation*, and a description of how humanity has evolved to its present form from cabbages (this last appears in one of the many lengthy footnotes mocking Darwin’s biological ideas). This parody linked Erasmus Darwin in the public mind with both the French Revolution and sacrilegious science and was in fact very funny. This contributed directly to the neglect of Erasmus Darwin in accounts of eighteenth-century intellectual history until quite recently.

The subsequent abandonment of Erasmus Darwin by the cognoscenti in the nineteenth century is unusual in its thoroughness, especially given Darwin’s reputation prior to Canning’s parody. After *Zoonomia* appeared in 1794, for example, Darwin was for a time widely considered the most important medical writer in England and was indeed the most popular scientific writer of the Romantic era. His poetry enjoyed a similarly elevated position for a time, with Samuel Taylor Coleridge declaring in 1797 that he was the “first literary character of Europe,” a direct influence on Coleridge as well as on William Wordsworth, Percy Bysshe Shelley, and of course Darwin’s collaborator William Blake. Shelley and his colleagues spoke so much of Erasmus Darwin and his devotion to science that Mary Shelley included an anecdote she had overheard about Darwin, in which he allegedly gave life to a piece of vermicelli, in the introduction to the 1831 edition of *Frankenstein*. It is unclear what she actually overheard, as Darwin certainly had not brought pasta to life, but one possibility may lie in a *Temple of Nature* reference to *vorticellae*, or “wheel animals,” microorganisms which were in his time believed to arise in rain puddles via spontaneous generation.

Influence on Charles Darwin

Despite his prominence in literary and scientific circles in the eighteenth century, Erasmus Darwin was largely ignored by both disciplines through the nineteenth and much of the twentieth centuries. Even his most famous descendant, Charles Darwin, attempted to distance himself from his grandfather’s work, for the simple reason that he preferred that his own ideas not be seen as derivative. This was not an idle worry; in 1860, in a review of the first edition of *On the Origin of the Species*, Bishop Samuel Wilberforce noted the many similarities between the works of the grandfather and the grandson:

We do not think that, with all his matchless ingenuity, Mr. Darwin has found any instance which so well illustrates his own theory of the improved descendant under the elevating influences of natural selection exterminating the progenitor whose specialities he has exaggerated as he himself affords us in this work. For if we go back two generations we find the ingenious grandsire of the author of the ‘Origin of Species’ speculating on the same subject, and almost in the same manner with his more daring descendant. (254)

Wilberforce’s review also takes note of the philosophical attacks by Canning and the *anti-Jacobin* poetry, suggesting that the younger Darwin has effectively answered their criticisms.

Ultimately, the task of reviving the elder Darwin’s reputation was left to his grandson, who in 1879 published the definitive biography, *The Life of Erasmus Darwin*, which has long been the standard source for all others who might wish to write about the man. Curiously, all editions prior to 2002 were expurgated, missing some 16% of Charles Darwin’s original manuscript, material which had been excised by his daughter, Henrietta. Henrietta had helped Darwin with some of his previous books, and he trusted her judgment as an editor. She cut down the manuscript after criticizing it for being too long; given that in the 2002 edition, the body of the book only runs 92 pages in length, this seems unlikely. Furthermore, the excised material

included a glowing tribute to Erasmus Darwin's brilliance and prominence across a range of disciplines, suggesting an attempt to preserve Darwin's reputation as the superior, and more original, intellect in the Darwin family tree. Still, the book remains the standard reference on Erasmus Darwin and the source cited by all others.

Eric Kandel

Androulla Ioannou and Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Introduction

Eric Kandel is a well-known neuroscientist for his research on memory and learning for which he shared the Nobel Prize in Physiology or Medicine in 2000. His breakthrough came through his pioneering work with *Aplysia*, which provided a wealth of information regarding nonassociative learning and its forms.

Eric Kandel's Biography

Kandel was born in Vienna on the 7th of November 1929. His mother, named Charlotte Zimels, was born in 1897 in Kolomea, which was at that time part of the Austro-Hungarian Empire. Kolomea is now a part of Ukraine and has been renamed Kolomyia. She came from a well-educated Jewish middle-class family. His father, Hermann Kandel, was born in 1898 in Olesko, a small town and then part of Austro-Hungarian Empire, now part of Ukraine, and was brought up in a poor family. At the beginning of World War I, his parents moved to Vienna, Austria, where they met and married in 1923. By the time they had their first child, Lewis, his father was the owner of a toy store. Eric Kandel was born 5 years later. They lived in a middle-class neighborhood, in a small apartment, and as both of his parents were occupied with the toy business, a housekeeper was looking after the children. Approximately when Eric Kandel was 10 years of age, he moved to Brooklyn, in the United States, with his family. His parents had to work hard to bring it along and adjusting was difficult. However, Kandel speaks highly of his parents for their determination and hard work to raise him and

his brother; they were not only successful in their jobs but managed to support both of their children on their chosen paths. After their relocation, Kandel had already involved in an elementary school, of which he graduated in 1944. After he graduated from the Yeshivah of Flatbush Elementary School, he went to the Erasmus Hall High School, a local public high school in Brooklyn. By then, Kandel was already fluent in several languages, including Hebrew and Greek, and was involved in several activities including, among others, soccer, music, and writing. He then applied to Harvard College and managed to be admitted and earn a scholarship as well. He majored in European history and literature. After some interactions he had with some psychoanalysts, he became more interested in understanding the human mind and that was determinant in furthering his studies by becoming a medical doctor. During his studies, he became increasingly interested in the biological basis of the mind. By 1956, he graduated from the New York University School of Medicine. He then joined a research team in Harry Grundfest's laboratory at Columbia University where they were dealing with research on a cellular basis. Grundfest was then a pioneer on the use of oscilloscope to measure action potential conduction velocity on the axons of neurons. After the intracellular recordings of electrical activity of the cerebral cortex of vertebrates done with Grundfest's team, Kandel's interest was directed to the study of the electrophysiology of neurons of invertebrates, influenced by the work of Kuffler. The shift occurred from Kandel's belief that the mechanisms of memory storage were possibly well preserved in phylogeny and that the cellular analysis of learning in low-level animals would reveal universal mechanisms that were also found in more complex organisms. His belief was validated shortly after. The Official Website of the Nobel Prize (2018).

Around 1957, when Kandel joined the Laboratory of Neurophysiology at the US National Institutes of Health, he focused on the study of the hippocampus. William Beecher Scoville and Brenda Milner were working at that time on the hippocampus and noticed that after hippocampus

excision, a patient no longer had the ability to form new memories. Kandel was greatly intrigued yet puzzled by the findings of these researchers and begun examining the electrophysiology of hippocampal pyramidal neurons. At that time, he was working with Alden Spencer, another great neuroscientist who was also interested in the biology of learning and memory. They managed to provide electrophysiological evidence for the formation of action potential in the dendrites of hippocampal neurons, not only in the axons as it was previously suggested. These dendritic action potentials were the trigger for firing at the axon hillock. They also recorded spontaneous pacemaker-like activity in these neurons; they noticed that firing took the form of bursts of spikes. Lastly, their research outcomes indicated the presence of strong recurrent inhibitory processes in the hippocampus resulting in prolonged inhibition. Kandel began to realize that memory storage must rely on modifications in the synaptic connections between neurons and that the complexity of the connections found in the hippocampus made it an inappropriate system for the study of synapses. That's when he selected the simplest animal model for his study, *Aplysia* (sea slug). He conducted electrophysiological analyses of the synaptic changes involved in learning and memory storage and provided breakthrough information that seemed to correspond to the simplest forms of learning (habituation, sensitization). It is noteworthy to mention that during the years 1963–1965, Kandel begun his academic career as an instructor in the Department of Psychiatry. In 1965, he accepted the position of associate professor at New York University, and it was during that time period that he started working with *Aplysia*. By 1974, he became a professor, in the Department of Physiology and Psychiatry, in Columbia University, and later the director of the Center for Neurobiology and Behavior. Around 1984, he became a senior investigator at Howard Hughes Medical Institute at Columbia University. The Official Website of the Nobel Prize (2018).

On a personal level, Kandel has already met and married (1956) the French, Denise Bystryn. They had two children, Paul and Minouche, and

are currently proud parents and grandparents as well, as all family members have thrived. His wife is a professor in the Department of Psychiatry and in the School of Public Health at Columbia University and has worked extensively on the field of addictions and drug abuse in adolescents. For nearly 40 years, they have been living in Bronx, and together they enjoy a variety of hobbies and interests, visual arts, classical music, and opera, and they passionately collect art and antiques. The Official Website of the Nobel Prize (2018).

Kandel's experimental research work has been extensive and greatly influential for the scientific world. He counts numerous publications that have not only been enlightening but also determinant for the course of future research. For his excellence and achievements, he has received more than 20 awards among them the Lester N. Hofheimer Prize for Research of the American Psychiatric Association (1977), the American Association of Medical Colleges Award for Distinguished Research in the Biomedical Sciences (1985), the Gairdner International Award of Canada for Outstanding Achievement in Medical Science (1987), the Harvey Prize in Israel (1993), the Wolf Prize in Biology and Medicine (1999), and the Nobel Prize in Physiology or Medicine (2000) which he shared with two other colleagues. He has also received honorary degrees from nine universities, three of which are European. The Official Website of the Nobel Prize (2018). His awards indicate worldwide recognition of his work.

Kandel's *Aplysia*

Aplysia became known to the scientific world through the pioneer work of Kandel which provided a wealth of information regarding non-associative learning and its forms (habituation and sensitization). *Aplysia* is a species of sea snail, commonly referred to as sea hares because of their posterior tentacles that protrude like ears do in hares. Among low-level organisms, *Aplysia* has become a fitting model for studies of how neurons and neural circuits regulate behaviors.

What attracts scientists into studying them are their simplicity and the huge size of their neurons, which are easy to manipulate and work with. Also, *Aplysia* exhibits abilities on learning establishing thus its appropriateness for applying cell biological approaches to the investigation of learning and memory mechanisms Moroz (2011). Of particular interest to Kandel and colleagues was the gill and siphon-withdrawal defensive reflex of *Aplysia*. *Aplysia* has a mantle cavity on its dorsal surface that protects the gill. The gill lies beneath the mantle shelf, which terminates at the back of the cavity in a fleshy, funnel-shaped spout, the siphon, which contracts to eject water from the gill. A two-component reflex is triggered when stimulation is applied to the siphon (mantle shelf) causing both the siphon and the gill to be retracted, protecting the organism from potential threat. These two components consist of two involuntary reflexes, the so-called siphon-withdrawal reflex (SWR) and the gill-withdrawal reflex (GWR). The gill- and siphon-withdrawal reflex (GSR) is mediated by distinct neuronal pathways, enabling scientists to record activities on the synaptic and neuronal level and to directly link synaptic plasticity to behavioral plasticity. The neural circuits of these reflexes are comprised of monosynaptic connections from sensory neurons to motor neurons, as well as polysynaptic connections containing excitatory and inhibitory interneurons. Kandel and associates work on this invertebrate animal regarding the cellular mechanisms underlying habituation and sensitization observed that while light siphon stimulation would naturally cause retraction, repetitive siphon stimulation produced short-term habituation lasting for a few hours. On the other hand, long-term habituation was demonstrated by repeating multiple training sessions across several days. A single habituation training session consisting of regular trials separated with a time interval of 30 s produced typical reductions in response to the siphon-withdrawal reflex. The replication of these training sessions once per day for 4 days produced a progressive buildup of habituation within each session. Habituation preservation was tested the next day and weeks 1 and 3 after

training, and when compared to group, the experimental group exhibited greater habituation. The gill-withdrawal component of the reflex was also tested for long-term habituation with the same procedures showing that siphon training produces long-term habituation in both components of the reflex Castellucci, Pinsker, Kupfermann, Kandel (1970). Furthermore, in another series of experiments, noxious shocks at the rear produced an increase in the siphon-withdrawal reflex and in the gill-withdrawal reflex. A single shock increased the reflex for 15 min to an hour. After repeated shocks, sensitization seemed to last up to several weeks. Four brief noxious electrical shocks were applied daily for 4 consecutive days. Sensitization retaining was measured again at day 1 and weeks 1 and 3. Also greater sensitization was observed with the addition of more shocks and by spacing the training sessions (two daily shocks within 10 days) Pinsker, Hening, Carew, Kandel (1973).

Generally it was indicated that short-term and long-term habituation results from homosynaptic depression of excitatory neurotransmission, while heterosynaptic facilitation of the sensorimotor connection caused sensitization. Habituation was not brought up by changes in the activity of sensory or motor neurons. Specifically sensory neurons release less neurotransmitter because of changes in calcium channels regulating neurotransmitter release, leading to the functional inactivation of the synapse in the long term. Nevertheless habituation still occurs after direct electrical stimulation of the motor nerve, avoiding that way the sensory receptors. This is essential as it reveals that the reduction in response is not due to sensory adaptation. Furthermore, motor fatigue is also eliminated by showing that direct stimulation of the motor neurons can still provoke a normal reaction after habituation has occurred. Carew (1984) provides more detailed description of the work with *Aplysia*.

Conclusion

Eric Kandel's life story and academic path, apart from being motivational, have left the academic

society with solid grounds to work on and have provided breakthrough information adding up to the understanding of how the human mind works. His work focused on the physiological basis of learning under which he explored short- and long-term memory, neural circuits, and synaptic processes through experiments with *Aplysia*.

Erotomania

Martin Brüne
LWL University Hospital Bochum, Ruhr-
University, Bochum, Germany

Synonyms

de Clérambault's syndrome

Definition

Delusional conviction of being loved by another person

Introduction

Erotomania (de Clérambault's syndrome) is defined as the delusional conviction of being loved by another person. It usually involves morbid infatuation and "projection" of the affected individual's own attitudes onto the perceived "love object" (Enoch and Trethowan 1991). The incidence rate is considerably higher in women than men, and the "love object" is usually a man of high social status. Anecdotal descriptions date back to ancient writings, whereas the first scientific description was published by French psychiatrist de Clérambault in the 1920s (Berrios and Kennedy 2002).

Erotomania is quite uncommon in clinical practice, though its dramatic effects on both the affected individuals and their "love object" has inspired scholars from various psychiatric "schools" to speculate about the etiology and pathogenesis of erotomania. For example, from the 1950s to the 1970s erotomania was primarily interpreted in psychodynamic terms, similar to Freud's interpretation of paranoia, while the advent of neuroimaging technology has sought to discover brain abnormalities associated with the syndrome (reviewed in Brüne 2003). In DSM-5, erotomania features among the delusional disorders (erotomantic type),

similar to previous versions of the manual, though the condition may occur in schizophrenia, schizoaffective disorder, and bipolar disorder, as well as in cases with a defined brain damage (Brüne 2003).

In any event, none of the conventional approaches has accounted for the striking sex differences in prevalence rate of erotomania, characteristics of the "love object," and the behavior associated with the condition, which typically includes harassment and sometimes severe incidents of stalking (Mullen and Pathé 1994).

Sexual Strategies Theory

While the formation of delusional beliefs may either entail cognitive biases including "jumping to conclusions" and a "bias against disconfirmatory evidence," or a deficit in information processing concerning emotionally relevant stimuli combined with aberrant belief evaluation (Bell et al. 2006; Coltheart et al. 2007), not spelled out in greater detail in this entry, the content of erotomantic delusions may best be framed in an evolutionary psychological perspective.

According to "Sexual Strategies Theory" (Buss and Schmitt 1993), throughout evolutionary history, men and women have faced divergent adaptive problems regarding parental investment in potential offspring, with direct consequences for courtship and mating behavior. That is, in mammals the minimum parental investment of females (gestation, lactation) exceeds by far the minimum investment of males (insemination). Following this logic, a female's reproductive success is constrained by the resources a potential mate is willing to provide. Thus, females would be expected to be "choosier" concerning mate selection (Darwin 1871; Trivers 1972). In contrast, males' inclusive fitness would rise with the number of partners, which is why males are intrasexually competitive for access to females. Even though cultural practices and norms may differ considerably, these principles also apply to human mating behavior. The attractiveness of human males for women therefore entails high social status and wealth,

whereas physical attractiveness and other signals of fecundity may reflect female reproductive qualities (Buss and Schmitt 1993). Such differences in “mate value” may also account for the fact that women usually prefer older men as partners, whereas men, on average, prefer younger women, because the “mate qualities” of both sexes are related to age.

Another consequence of the disparate parental investment concerns the duration of an intimate relationship. Put another way, short-term mating favors the number of potential sexual contacts and offspring, whereas long-term mating increases the likelihood of survival of offspring. Accordingly, women would be more likely to seek long-term mates due to their higher parental investment, whereas men tend to prefer short-term relationships to maximize their reproductive success (Buss and Schmitt 1993).

Erotomania Reconsidered in Light of Sexual Strategies Theory

Prima facie, the behavioral pattern associated with erotomania seems to be compatible with a long-term mating strategy, distorted and pathological as it may be expressed. Accordingly, the following predictions would arise from this hypothesis:

Erotomania is more likely to occur in adult women than men. Individuals with erotomania are likely to be unmarried, divorced, or, if married, in an ambivalent relationship. Demonstration of chastity and enhancement of attractiveness may be relevant for women with the condition.

In women with erotomania, the “love objects” are expected to be socially high-ranking (older) men, whereas male erotomaniacs tend to choose physically attractive (younger) women. When engaging in long-term mating, men are expected to activate mechanisms to detect sexual infidelity to increase likelihood of paternity (jealousy). Therefore, erotomania in men is likely associated with sexual jealousy, which may include violent harassment or stalking of their “love objects.”

Brüne (2003) has reviewed about 250 case reports of erotomania published in the scientific literature and found the predictions derived from

Sexual Strategies Theory largely confirmed. Aside from a striking similarity of the clinical picture across cultures and ethnic backgrounds, the survey revealed that more than two thirds of the case reports were about women with erotomania. Female preponderance would have been even larger, if more recent interest in forensic consequences of erotomaniac stalking (more prevalent in males) were taken into account. As predicted, erotomaniac subjects were likely to be unmarried, divorced, or, if married, in an ambivalent relationship. Moreover, in spite of limited information about attractiveness, women seemed to be more likely to enhance their outer appearance and tended to remain chaste. In female erotomania most “love objects” were socially high-ranking (older) men, whereas men with the condition tended to stalk physically attractive (younger) women.

Harassment was prevalent in both sexes, though violent stalking was much more frequent in men with erotomania (Brüne 2003).

Conclusion

Erotomania, the delusional conviction that a person is loved by another person, represents a clinical syndrome that can occur in a broad spectrum of neuropsychiatric disorders. Erotomania may be understood as a pathological variant of a long-term mating strategy that is more likely to occur in women, because of women’s higher parental investment in potential offspring. Male erotomania is more frequently associated with violent behavior which is primarily directed towards the pursued “love object,” her kin, or persons who are perceived as “rivals” (Mullen and Pathé 1994). The difference in violent behavior between men and women with erotomania may reflect the evolutionary condition of uncertain paternity, which caused the emergence of male sexual jealousy as a strategy to minimize the risk of cuckoldry, i.e., investing in another man’s offspring (Buss and Schmitt 1993; Daly et al. 1982).

Taken together, the evolutionary psychological perspective may contribute to the understanding of pathological variants of cognitions, emotions and behavior.

Error Management Theory

Shaunna N. Souve and Joseph A. Camilleri
Westfield State University, Westfield, MA, USA

Definition

Error management theory is a middle-level evolutionary theory that explains cognitive biases.

Error management theory (EMT), proposed by Haselton and Buss (2000), explains the evolution of cognitive biases. EMT suggests that certain

psychological mechanisms, such as the ones that help form decisions, evolved because they had a reproductive advantage (Haselton and Buss 2000). One such mechanism is a proneness to make either a *false positive* (see “► [False Positives](#)” entry) or a *false negative* (see “► [False Negatives](#)” entry) in judgments when the outcome is uncertain. A false positive (also called a Type I Error) is when you identify something as true when it is false, such as perceiving a situation as dangerous when it is not, whereas a false negative (also called a Type II Error) is when you identify something as false when it is true, such as perceiving a situation as safe when it is dangerous (Haselton and Buss 2000). Adaptive biases for these errors may have been useful in ancestral situations. For example, there would be greater costs in mistaking dangerous situations as not dangerous than mistaking safe situations as not safe. We are biased toward the error that maximizes benefits while minimizing costs (Haselton and Buss 2000).

Haselton and Buss (2000) used EMT to explain women’s underestimation of men’s commitment levels (called the “► [Commitment Skepticism](#)”, see entry) and men’s overperception of women’s sexual intent (called the “Sexual Overperception Bias”, see entry). The *commitment skepticism bias* suggests women possess “intention-reading” adaptations that function to underestimate a potential mate’s commitment level, to avoid the cost of independently raising offspring, for example. Since women’s minimal obligatory parental investment is higher than that of men’s, it would be costly to believe a mating partner has a long-term commitment to the relationship when they do not (false positive) than to believe a mating partner does not have a long-term commitment to the relationship when they do (false negative). To test this hypothesis, Haselton and Buss (2000) compared cross-sex perceptions of commitment intent, with same-sex perceptions of commitment intent, and found that women’s ratings of men’s commitment avoidance was greater than men’s self-reported measures.

A second study tested the *default model hypothesis*, which suggests that men use their own sexual desire to gauge women’s sexual intent, resulting in men’s overestimation of women’s sexual intent

(Haselton and Buss 2000). Since men's minimal obligatory parental investment is lower than that of women's, it would be costly to miss possible mating opportunities. False negatives (i.e., believe a woman is not sexually interested when they are) would therefore be more costly than false positives (i.e., believe a woman is sexually interested when they are not), which is why theoretically men would be expected to overestimate women's sexual interest. Empirically, they found that men's ratings of women's sexual intent were greater than women's reports of their own sexual intent.

Haselton and Nettle (2006) broadened the applications of error management theory to explain auditory looming, food aversions, avoiding the ill, and sinister attribution error. Auditory looming refers to sounds that rise and fall in intensity. Neuhoﬀ (1998, 2001) found that sounds increasing in intensity were perceived as moving faster than sounds decreasing in intensity. Neuhoﬀ explained this effect as an evolutionary adaptation to becoming prepared for an oncoming source. When an individual hears a sound increasing in intensity, it is better to be prepared for a swiftly approaching source than to assume it is something harmless (Neuhoﬀ 2001). If the oncoming source was a predator, early preparation has no potential costs, whereas late preparation has a very high cost to reproductive success and survival. As a result, natural selection would favor psychological mechanisms that allowed a quicker response to sounds increasing in intensity (Neuhoﬀ 2001).

Error management theory can also explain food aversions. When a person becomes sick after ingesting something, they tend to associate the sickness with that food or drink. Such aversions motivate people to avoid foods that now produce an unpleasant reaction (Garcia et al. 1966; Rozin and Kalat 1971). Those with an ability to quickly learn which foods made them sick from a single trial would have had a reproductive advantage by later avoiding these sources of sickness. In ancestral environments, it would have been adaptive to avoid eating toxic foods (Haselton and Nettle 2006). Even though there is a cost of decreased calorie intake, the possibility of ingesting toxic foods has a greater cost and is a greater threat to reproductive success and survival

(Haselton and Nettle 2006). A false positive would be the least costly error to make because one would avoid the chance of possibly ingesting toxic food. A false negative has the most cost associated with it because claiming a food as nontoxic when it actually is would have resulted in sickness or even death.

EMT also applies to beliefs and actions toward sickness. Little to no proof is required to believe someone is sick, as a result, avoiding them. However, people tend to need much more evidence to prove recovery or absence of illness (Kurzban and Leary 2001; Park et al. 2003). This can be applied to individuals' fears of becoming contaminated with the illness of others. When a family member or friend is sick, people tend to maintain physical distance from them to avoid catching the sickness, even if people are aware that the risk is low just from being in the same room (Haselton and Nettle 2006). These actions can be explained as an adaptation to avoid the risk of becoming ill. The cost of not avoiding someone with an illness or disease is greater than the cost of avoiding someone who is not contagious. People therefore tend to keep their physical contact to a minimum with those who are ill. For example, even though people knew AIDS was not contagious by only being near them, it was found that participants felt uncomfortable after only 5 min of contact with the individual. It was also found that participants were uneasy about the idea of having one of their items of clothing being worn by a person with AIDS (Bishop et al. 1991; Rozin et al. 1992). Disease avoidance psychological mechanisms may reduce the chance of getting sick, but it produces more false alarms (Haselton and Nettle 2006).

The sinister attribution error has also been explained by EMT. This attribution error is when people exaggerate their perception of others' intentions based on body language and verbal communication (Haselton and Nettle 2006). In ancestral environments, when visiting an unknown group, it would be less costly to over-evaluate the possible negative intentions of their members than to be unaware of the negative social evaluations they have of you, since this could have resulted in abandonment, direct aggression, or even death (Baumeister and Leary 1995). As a result, people in new social situations become

hypervigilant of their surroundings and the actions of others around them and may misperceive simple gestures as hostile or negative (Baumeister and Leary 1995).

Error management has the potential to explain a variety of cognitive biases. In addition to the literature reviewed here, EMT has also been applied to dangerous animals, noises of uncertainty, allergies, the illusion of animacy, decoding courtship signals, and the illusions of control (Haselton and Nettle 2006). Difficulty in this line of research is measuring costs and benefits related to false positives and false negatives.

Conclusion

Error management theory explains the evolution of cognitive biases, where people are more prone to either making false positives or false negatives depending on which error maximizes benefits while minimizing costs. This approach has been used to explain cognitive biases in many domains such as avoiding the ill, taste avoidance, sound perception, and perception of others' intent.

Error Management Theory: Benefit and Cost Asymmetries

Jessica F. S. Jacobs and Joseph A. Camilleri
Westfield State University, Westfield, MA, USA

Definition

Error management theory suggests that when people make judgments of uncertain outcomes, cost and benefit asymmetries in making Type I and Type II errors result in the evolution of cognitive biases that either minimizes costs or maximizes benefits.

Decisions under uncertainty can be wrong in one of two ways: Type I errors (i.e., false positives) are a prediction of X when X is *not true* or Type II errors (i.e., false negatives) are a prediction of *Not X* when X is *true*. An example of Type I error is when a man believes there is sexual interest from a woman when there is not, whereas a Type II error would be when a man believes there is no sexual interest from a woman when there is (Haselton 2007). Error

management theory (Haselton and Buss 2000) was developed to explain proneness to making either Type I or Type II errors as a type of cognitive bias. The theory suggests that certain errors in judgments in ambiguous situations are neither irrational nor arbitrary but may be adaptive. Due to the costs and benefits of either error rarely being symmetrical, evolutionary processes would have selected a decision-making rule favoring one error over another to minimize the costs and maximize benefits.

Cost and benefit asymmetries of judgments where outcomes are uncertain can therefore be the driving force in the formation of many cognitive biases (Haselton and Buss 2000). Although a decision may both minimize a cost and maximize a benefit, there may be situations where Type I and II errors have equal benefits but unequal costs, and so we would expect a bias toward minimizing the costs. In this case, the cost asymmetry guides the decision. If, however, a scenario where Type I and II errors have equal costs but unequal benefits, we would expect a bias toward maximizing the benefits. In this case, the benefit asymmetry guides the decision.

Continuing the example of sexual interest, a Type II error (believing there is no sexual interest when there is) would have been rather costly to men. Mistaking sexual interest when none is present is not as costly as mistaking a lack of sexual interest because the latter results in a missed mating opportunity. Haselton and Buss (2000) suggest this is why men more consistently misperceive benign interactions with women as signs of sexual interest. Another commonly cited example can be seen in the potential misidentification of an object. Many people are more prone to mistaking sticks as snakes, but are not prone to mistaking snakes for sticks. There are no discernable differences in the benefits of making either mistake, but there are certainly differences in the costs.

The impact of asymmetries in the costs and benefits of Type I and Type II errors can also be seen in decisions we make when engineering products. Haselton and Buss (2000) used smoke detectors as an example. Smoke detectors are designed to have a low threshold for detecting smoke and sounding the alarm. While this low threshold may result in more “false alarms” (i.e., Type I error or false positives), they are far less costly than the

smoke detector failing to sound resulting in a false negative and people being unaware of a fire. For this reason, and to minimize the potential cost, smoke detectors are manufactured with a bias toward false positives (Haselton 2007).

Error management theory may also help us understand more complex manifestations of Type I and Type II errors because cost and benefit asymmetries of either error may be moderated by other factors. For example, the sexes may differ in the degree to which an incorrect decision is costly or beneficial, resulting in sex differences in cognitive biases. Since men can maximize fitness through increased mateships, and women can maximize fitness from a higher-quality long-term relationship, the costs and benefits of misperceiving interests from the opposite sex may also differ. When misperceiving sexual interest, it would be costly for men to assume no sexual interest when there is; however, such an error would not be as costly for women. When misperceiving relationship commitment, it would be more costly for women to assume long-term commitment when there is not, whereas such an error would not be as costly for men. Unsurprisingly, due to the tenets of EMT, women were more prone to showing commitment skepticism, and men were more prone to showing overperception of women’s sexual intent (Haselton and Buss 2000).

A difficulty in this line of research is to account for all costs and benefits given a scenario because there may be multiple costs and benefits that are asymmetrical for a particular decision. Mathematical modeling and multiple empirical tests under different cost-benefit conditions would help isolate the conditions under which cognitive biases may emerge.

Cognitive biases do not necessarily make people correct more often than they are incorrect. Some psychologists have concluded that cognitive biases are shortcoming or irrational due to this possibility of being wrong (Tversky and Kahneman 1974). EMT does not claim that the cognitive biases developed through evolutionary processes help current men and women be right more often than they are wrong. However, EMT reframes these biases and views them not as a weakness but as an adaptation, known as *adaptive errors* (Buss 2001). EMT explains the tendency

for thought processes and behaviors to be more attuned to what choice will lead to instances where survival and ultimately reproduction are the most likely outcome (Johnson et al. 2013; Haselton and Buss 2000).

Error management theory can be used to understand biases, due to asymmetrical costs and benefits in many domains. Johnson et al. (2013) provided a nice summary of topics to which error management theory has been applied, such as belief in god, antipredator actions, perceiving enemy intentions, and overconfidence, among many others. Considering humans and nonhuman animals are faced with numerous situations where a decision needs to be made about an unknown outcome, error management theory has the potential to explain a wide variety of thinking processes and behaviors.

Essentialism and Speciation

Mark Fedyk

Department of Philosophy, Mount Allison University, Sackville, NB, Canada

Introduction

Speciation is the process by which a new species is propagated from an older species. The process of speciation can be driven either by natural selection or any of the other evolutionary forces, although, as Darwin argues across the first two chapters of *On the Origin of Species* (Darwin 2008), artificial selection can also be a cause of speciation.

Speciation is widely believed to refute the thesis that species can be defined by essences. This argument is one of the key reasons why essentialism – a metaphysical doctrine about how all natural kinds are to be defined – has receded in popularity.

Essentialism

Aristotle first defined an essence as the *to ti ên einai* – which translates as “the what it was to be” – of something (Cohen 2016). Roughly two millennia later, and in the course of arguing against essentialism, John Locke puts it slightly differently, “Essence may be taken for the very being of any thing, whereby it is, what it is” (Locke 1694, p. 231), or put still another way, essentialism is an answer to the question: What make some kind of things *that* kind and not some other kind? The answer is that all of the things which are members of the relevant kind must have a common set of properties and that this set properties must occur in *all* and *only* the individuals that, when collected together, form the relevant kind. Furthermore, these properties usually, but

not always, are said to be intrinsic, unchanging, or ahistorical – typically meaning that no accidental occurrence or contingent force can cause the loss of any essential properties. The relevant set of properties is the *essence* of that kind.

Essentialism has an impressive historical pedigree. Many scientists and philosophers have held the position that all natural kinds, including all species, were defined by their essences. Aristotle is probably the first Western scientist to hold that essences must be posited in order to explain the organized diversity of the biological world. The connection between the biological sciences and essentialism remained strong until Darwin, for, among many other scientists, Linnaeus notably held that essences defined species (Larson 1968).

For the purposes of this entry, essentialism has three important logical implications. Let us assume that some kind *K* is defined by the instantiation of properties *x*, *y*, and *z*, which are together the essence of *K*. The first implication is that there can be nothing else but the members of *K* which have all three of these properties: it must be *all* and *only* things that are *K*s which have *x*, *y*, and *z*. Now, suppose that something which is a *K* loses property *x*. It follows that this individual is, the moment it loses *x*, no longer a *K* – that is the second implication. Finally, the third implication is that the boundary between kinds is fixed and exact. There should be no vague or non-sharp boundaries between kinds, there should be no intermediate forms which can put just as easily placed into one kind as another, and the boundaries between kinds cannot shift over time.

Species and Essentialism

We will now review two overlapping scientific arguments for why it seems extremely doubtful that species are defined by essences.

First, it is probably the case that not a single essence has been found anywhere in the natural world. For example, what trait occurs inherently in all and only *Myocastor coypus* and no other species? *Homo sapiens*? *Sepia apama*? Although it has proven difficult to discover essential properties, there is no corresponding difficulty in, first, discovering species and, thereafter, organizing

species into any number of different taxonomic systems. There are thousands and thousands of examples from post-Darwinian biological science which show that scientists can make sense of the organized diversity of the biological world without positing essences; this history of successful taxonomy explains why systems of biological classification which presuppose essentialism have fallen out of favor (Ereshefsky 2000).

There are also compelling theoretical reasons to doubt that species can be defined in terms of essences – reasons that are independent of the question of whether or not any essential properties have been discovered. Selection, mutation, migration, and genetic drift are, among other evolutionary forces, constantly inducing changes in the genetic basis of any single species. Even if there were a set of properties common to all and only some single population of a particular species, it would be very easy for, say, a mutation to eliminate that property. An essentialist would be compelled by the logic of her view to admit that the effects of this mutation mean that a new species has come into existence – but this inference would be out of step with the contemporary scientific consensus. A large amount of both genetic and phenotypic variation within any given species must be taken for granted, as this variation itself can be a conserved adaption (West-Eberhard 2003).

It is also worth examining the problem that is created for essentialism by constant evolutionary change. Speciation is a process that produces intermediate forms of organisms, and because of this, it is difficult to impose any principled division between generations of reproducing organisms that exactly and uniquely demarcate an ancestor species from one of its offspring species. Darwin expressed the difficulty this way: “we shall be compelled to acknowledge that the only distinction between species and well-marked varieties is, that the latter are known, or believed, to be connected at the present day by intermediate gradations, whereas species were formerly thus connected” (Darwin 2008, p. 422). The boundary between the kind of an ancestor and the kind of the offspring is almost always vague and indeterminate; appearances to contrary can be by-products of a lack of access to the all of the intermediary forms produced during speciation.

This point holds even in cases of extremely rapid speciation. Consider a recent example of speciation in Galapagos finches that occurred in only two generations (Lamichhaney et al. 2018). In 1981, a single male *G. conirostris* arrived in an island where *G. conirostris* were not already present. This bird mated with two member of an endemic finch species, *G. fortis*, and the DNA of the parent birds and their offspring was collected and tracked by a team of scientists. The first generation of offspring were hybrids who were nevertheless fertile – but they were unable to mate with any of the endemic species on the island due to differences between the song of the hybrids and the songs of the endemic birds. Inbreeding among this first generation of hybrids leads to a third generation of finches with larger bodies and beaks than the other finches on the island, allowing birds in the third generation to occupy a previously empty environmental niche and subsequently establish itself as the newest species of the Galapagos finches.

It is not clear how an essentialist can offer a plausible scientific analysis of this case. The contemporary and standard view – which is a non-essentialist analysis – would hold that, in this example, there are at least three species: the original male *G. conirostris*, the endemic *G. fortis*, and the new species produced by inbreeding. But the hybrid birds are inherently hard to classify: They are either unusual *G. conirostris* or unusual *G. fortis* or some forth but very short-lived species. The most important point is that there is no principled way of solving this problem. However, recalling the implications from above and overlooking the problem of locating properties unique to all and only the hybrids, an essentialist would be forced to conclude that the hybrids were a short-lived separate species and therefore that the number of species in this example can be not less than four.

Speciation is a drawn out process that produces a large number of intermediate forms that cannot be uniquely classified on principled grounds. As Darwin noted, we often lack access to these forms and can see only the beginning and the end – or even just the end – of a process of speciation. This can give the appearance that the boundaries between species are more exact than they really

are. A nonessentialist can see the diversity of life differing in degrees and, only where the differences are large enough, differing in kinds. An essentialist, by contrast, must see all biological life as though it differs in kinds.

Nonessentialist Definitions of Species

The most common response to these and other considerations has been to abandon essentialism. This means that a new definition of what makes a set of individual organisms members of a common species must be found.

One popular alternative to essentialism is the view that species are *homeostatic-property-cluster kinds* (Boyd 1999). According to this theory, kinds are defined by sets of properties that tend to co-occur, but need not co-occur as a matter of necessary. Knowing that something has one or two properties makes it likely but does not make it certain that it also has some further properties in the relevant set. The reason these predictions typically work is that at least some of the properties in the relevant set tend to cause their co-occurrence: For example, the presence of a certain gene makes it likely but does not guarantee the presence of a certain wing geometry in organisms with that gene. A particular species concept, then, picks out whatever HPC kind – if indeed there is one – that best explains why that particular concept can play a role in fruitful scientific theorizing.

If species are defined by sets of HPC properties, then intermediary forms and both genetic and phenotypic variety cause no difficulty; since HPC kinds can have vague or indeterminate boundaries, they can share some or all of their properties with other HPC kinds, and they are not so fragile that a change in the presence of a single trait (or property) changes the kind of thing which bears the change.

Conclusion

Today, few scientists and philosophers find essentialism plausible, and while Darwin's analysis of speciation is itself not wholly responsible for the

collapse of essentialism, it plays a large role: by calling attention to the ongoing processes of speciation that are driven by, inter alia, natural selection, Darwin dramatically increased the costs of combining a commitment to essentialism with a commitment to many of the core tenets of modern evolutionary biology.

[Ethnographic fieldwork](#); [Ethnographic literature](#)

Definition

Ethnography is a field method used to generate firsthand knowledge of a particular human group or a behavior of interest. This term also refers to the finished written product resulting from field research (i.e., an ethnography).

Introduction

Ethnography has been a hallmark of anthropological inquiry for over a century, and its use has grown across disciplines as a means to gather both quantitative and qualitative data. This method of systematic data collection includes the use of participant observation, where a researcher lives with a host community for an extended period in order to experience and record as many aspects of daily life as possible. The goal of ethnography for many anthropologists has been to facilitate holistic cross-cultural comparisons that ultimately generate emic (insider) and/or etic (outsider) interpretations of human culture and society.

Overview

Ethnographers typically study a cohesive group of people who interact regularly (a society). Multiple ethnographies contribute to *ethnology*. Ethnography is different from ethnology in that an ethnography usually documents a single community, where ethnology is the generalized body of knowledge pieced together through multiple ethnographies. Some examples of ethnological studies might consist of understanding variation in sociopolitical organization (e.g., bands, tribes, chiefdoms, states) or variation in subsistence practices (e.g., hunting/gathering, pastoralism, horticulture, or agriculture).

In the nineteenth century, many early anthropologists/ethnologists were interested in understanding variations in kinship, social structure, and behaviors within and between human societies, but they often formed interpretations from either library research or secondhand accounts. Many anthropologists point to the emergence of modern ethnographic fieldwork in the early twentieth century with the contributions of Bronislaw Malinowski (1922), Margaret Mead (1928), and Ruth Benedict (1934). By the mid-twentieth century, anthropologists such as Victor Turner (1967) and Clifford Geertz (1973) charged anthropologists

with tailoring their ethnographic approaches toward identifying veiled cultural meanings embedded in symbolism and language. Near the end of the twentieth century, ethnography's value in providing "objective" data was questioned by those who felt that scientific objectivity was impossible and that the ethnographic method produced misrepresentations tied to the perspective of the researcher (Clifford 1986; Marcus and Fischer 1986). The debate surrounding the validity of the ethnographic method is ongoing, and what constitutes a "proper" ethnography is continually under renegotiation among anthropologists.

Conclusion

Today, the use of ethnography has proliferated to become a common method of investigation across social science, medical, and business disciplines. The primary appeal of ethnography is that it places an emphasis on behavioral observation, rather than relying on what people report about themselves via questionnaires or surveys. While the purpose of ethnography has shifted away from the goals of early researchers to document "primitive" cultures, the method continues to enjoy recognition as an effective means through which to gather firsthand experiences about people and how they live their everyday lives.

Definition

Catalogs of species – typical behaviors

Introduction

Ethograms are directories or catalogs of species-typical behaviors. These behaviors, known as action patterns, are discrete, repeatable, identifiable acts that are described in detail according to characteristics such as their form, speed, duration, strength, and/or orientation. Ethograms often contain both written descriptions and pictures or diagrams so that action patterns are described in enough detail that another observer can recognize them.

Types of Ethograms

All behaviors included in an ethogram should be mutually exclusive and objectively described (Abeelen 1964; MacNulty et al. 2007; Wilkinson et al. 2010). Ethologists typically use two types of

Ethograms, Table 1 Example ethogram of male and female threespine stickleback mating behaviors (Adapted from Tinbergen 1951)

Male		Female	
Action pattern	Description	Action pattern	Description
Zig-zag dance	Lateral darting	Courting	Show belly to male
Lead	Bring female to nest	Follow	Follow male to nest
Point	Direct toward nest entrance	Enter	Enter nest
Shiver	Shaking while fertilizing nest	Spawn	Deposit eggs
Enter	Enter nest to fertilize eggs	Leave	Exit nest

Ethograms, Fig. 1 Kinematic diagram with transition frequencies for male threespine stickleback nesting behavior. Each box represents a behavior, with the arrows indicating the order in which they were observed to occur. Transition frequencies indicate the proportion of times that one behavior follows another. For example, poking was always observed to be followed by fanning. However, fanning behavior was followed by poking in most instances and darting a smaller proportion of times

descriptions when constructing ethograms. Motor patterns objectively describe physical movements made by the animal, while descriptions by consequence are behaviors defined in relation to the animal’s environment and are concerned with why the animal moved and the outcomes of a particular movement (Hardy and Heyes 1999). Specialized ethograms are specific to a particular developmental stage and/or sex. For example, an ethogram could be developed that describes stereotypic behavior of breeding male and female threespine stickleback fish (*Gasterosteus aculeatus*; Table 1). These behaviors do not normally occur outside of the breeding season.

Analysis of Ethograms

Ethograms allow researchers to describe sequences of behavior, with the ultimate goal of producing a kinematic diagram that summarizes the likelihoods of behavioral sequences. To make a kinematic diagram, the researcher records action patterns in the order in which they occur to create a sequence of events. This sequence is then used to create a matrix that lists the number of instances in which each behavior follows another, known as the number of transitions between behaviors. Transition frequencies can then be calculated, which quantify the percentage of time that one action pattern follows another. To make the kinematic diagram, arrows are drawn between behaviors to indicate their sequence (Fig. 1).

Conclusion

Ethograms standardize species-specific behaviors so multiple observers can analyze them consistently. However, they have several limitations (Martin and Bateson 2007). They may vary tremendously in the number of categories included and the extent to which they are described in detail. They are also unavailable for many commonly studied animals. Lastly, not all members of a species behave in the same way, which creates difficulties in describing species-typical behaviors.

Cause

Definition

Etiology is defined as the “cause of ill health.”

Introduction

The term “etiology” refers to the branch of science that deals with the cause of any disease. The Merriam-Webster dictionary defines “etiology” as *cause* or *origin*, which is commonly discussed in the context of ill-health (Dictionary 2006). It is derived from Greek words (*aitia* meaning cause and *logia* meaning study). The term “etiology” is used synonymously, widely in literature. Etiology is often described together with the pathogenesis (how the disease develops/evolves). The term “etiopathogenesis” is used to describe the process of development of disease with specific reference to the underlying etiology. The pathogenesis of a disease is mostly defined by its underlying etiology. For example, the pathogenesis of inflammation due to tubercular bacteria is different from that caused by herpesvirus. Etiology guides in the classification of diseases and their management.

Classification of Etiology

Etiologies can be classified in various ways. For example, etiology can be divided into infective and non-infective types. Infective etiologies result

in development of communicable diseases, and non-infective etiologies often result in non-communicable diseases. In developing and under-developed countries, infective etiologies attribute to major burden of illness. Noncommunicable diseases (NCDs) often result from lifestyle-related factors and attribute the major burden of diseases in most developed countries and several developing countries too.

Etiological factors can also be classified into biological, psychological, and environmental (sociocultural) factors (Kar and Tripathy 2019). “Biological” etiologi- cal factors are infections, deficiency of nutrients, genetic causes, traumatic causes, alterations in specific organ physiology, and metabolic causes. “Psychological” etiologi- cal factors like personality, adverse life experiences, and poor stress tolerance (increased perceived stress) might attribute to development of disorders/illnesses. “Environmental” etiologi- cal factors can be in the form of workplace/occupational hazards, pollution, exposure to ionizing radiations, climatic adversities, and epidemics.

Etiology can be understood and classified at the microscopic or gross levels. In the microscopic level, cellular (e.g., sickle cell anemia, megaloblastic anemia) and subcellular dysfunction (e.g., mitochondrial abnormality, lysosomal storage disorders) result in a disorder. At the gross level, the etiology of a disorder can be described basing on the dysfunction of a larger structure (organ). For example, hepatic failure and renal failure can cause delirium. Here, the cause of delirium is attributable to organs (liver and kidney).

The etiology of a disorder can be described on the basis of its pathogenesis, organ involve- ment, nature of the disease process, as well as clinical manifestations. For example, the etiologies of Creutzfeldt-Jakob disease (CJD) are described as infective (causative agent), neuro- degenerative (pathogenesis and organ involve- ment), as well as neurocognitive (clinical manifestations). Similarly, pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS) describes the etiologies as autoimmune (pathogenesis) and infection by *Streptococcus pyogenes* (causative agent).

Evolutionary Significance of Etiology

Etiologies of illnesses remained unclear for centu- ries. In the ancient days, people associated various causes of illnesses merely on the basis of assump- tions and observations, backed by their sociocul- tural beliefs and traditions. People attributed the causes of diseases like tuberculosis, leprosy, and mental illnesses to supernatural powers. The exact pathophysiological mechanisms of illnesses were unknown for long. With time, scientific evidences were generated and causal (etiological) attributions were changed (Kar 2019).

Ayurveda (one of the oldest system of medicine) deduced the etiologies of illnesses to three intrinsic bodily factors (*Vata*, air; *Pitta*, bile; *Kapha*, phlegm), together known as *tridosha* (Opler 1963). Hippocrates, the father of ancient medicine, had attributed the etiology of illnesses to disequi- librium of four important body fluids (sanguine, blood; choleric, bile; melancholic, black bile; phlegmatic, phlegm), which are classically known as “four humors of Hippocrates” (Bujalkova et al. 2001; Pappas et al. 2008). During that time most of the illnesses were attributed to diet, environment (climate), and society. Hippocrates attempted to demystify the illnesses by evaluating their etiolo- gies through keen observation and by negating the prejudices (Kushner 2013).

Presently, the cause of an illness is being established by meticulous history taking clinical examination and specific investigations. Over past centuries, investigation techniques have been developed exponentially, resulting in shifting of this paradigm. Currently, diagnosis is mostly based on investigational findings rather than clinical examination. xcessive relying on investiga- tions (to establish etiology) rather than using the clinical skills is being criticized (Hofmann and Welch 2017). There should be optimal use of clinical skills and judicious use of investigations to find out the etiology of an illness.

Establishing the Etiology

Association of etiology with a disorder (illness) cannot be judged by a single case or single study.

There are many confounding variables that may falsely establish an association between the etiology and disorder (which can simply be a chance association). However, if the association is established in multiple researches, in a larger population, at different points of time, using various research designs, then the etiology can be linked with the disorder with certainty.

In clinical research, etiology of an illness can be ascertained by adopting various research methodologies (Moola et al. 2015). Broadly, three different designs (epidemiological/observational) elicit the association between cause (etiology) and effect, which are (Fig. 1):

- **Prospective design:** It moves in the direction of cause (etiology) to effect. People exposed to various known etiological agents are followed over a period of time to look for disease occurrence. For example, people smoking cigarettes are followed up for occurrence of lung cancer.
- **Cross-sectional design:** Specified group of population (often diseased/ill) are evaluated at particular point or period of time for identifying the etiological agent. For example, all

patients with fever and jaundice are evaluated for hepatitis B virus infection.

- **Retrospective design:** It moves in the direction from effect to cause. People, who had already developed disease/illness, were evaluated for specific cause(s). For example, all patients with borderline personality disorder were evaluated for adverse experiences during their childhood.

Establishment of causality (etiology) can be ascertained through the strength of association, temporality of association, and specificity as well as consistency of association (Moola et al. 2015). The above research designs, applied in a larger population from time to time, generate evidences regarding association of etiological factors with illnesses.

Investigative procedures sometimes help in establishing the etiology. In clinical settings, various screening investigative procedures are used to ascertain the etiologies of specific abnormalities of health. For example, urine drug screen is used to detect the drug abused that is attributing to altered behavior in an individual, who had addiction. Similarly, toxicological screening is used for detection of poisoning; metabolic screening is used for

Etiology, Fig. 1 Various research designs for evaluating the etiological associations

detecting metabolic derangements; and HIV and hepatitis screening tests are used for detection of these infections. These screening tests can give information about specific etiologies.

The terms “sensitivity” and “specificity” are used in the context of tests or investigations used for identifying etiologies. These terms predict the accuracy with which an investigational procedure measures the association of an etiological agent and the illness (sensitivity) or non-association of an etiological agent with healthy state (specificity) (Hawkins 2005). Sensitivity measures the percentage of diseased population found to be true positive, whereas specificity measures the percentage of non-diseased population found to be true negative.

To establish the cause-effect association, causality assessment is recommended in pharmacovigilance (Ralph Edwards 2017). Drugs (medications) produce side effects. For example, steroids and antitubercular drugs (cycloserine, isoniazid) may produce psychosis. So, the drug here can be considered as the etiology of illness. Radiological (e.g., X-ray, computed tomography scan, magnetic resonance imaging) and sonological (e.g., ultrasonography, echocardiography, Doppler) investigations have been used for identification of various etiologies. For example, in Creutzfeldt-Jakob disease, there is signal alteration in the T2 images of magnetic resonance imaging at the basal ganglia. X-ray of chest may indicate about pulmonary tuberculosis. Hyperdense lesion in the computed tomography scan of brain may indicate hemorrhagic stroke. Specific modifications (e.g., use of contrast) are done in the radiological procedures to delineate specific location and nature of etiopathology. Electrophysiological investigations (e.g., electrocardiogram, electroencephalogram, and electromyogram) can be used for identification of specific disorders and sometimes their etiologies. For example, periodic complexes in electroencephalogram are seen in subacute sclerosing panencephalitis, T-wave abnormalities in electrocardiogram in lithium toxicity, and electromyogram in muscular dystrophies. Organ biopsy (e.g., liver and spleen biopsy in amyloidosis), culture of body fluids (e.g., blood culture for identification of

specific microbial organism), and hematological investigations (e.g., microcytic hypochromic blood picture in iron-deficiency anemia) are also useful in establishment of etiology. Establishment of etiology is often complex and challenging in mental illnesses. In mental illnesses, the clinician needs to do a detailed mental status examination and sometimes certain psychological assessments in addition to detailed history taking and physical examination, to establish the etiology.

Clinical Significance of Etiology

If illness is the effect, the underlying cause is referred as the “etiology.” An illness can have single etiology (one-to-one cause-effect relationship) or can have multiple etiologies (Kar 2019). Similarly, multiple etiologies can be associated with single illness. Tracing back to the etiology from the disease diagnosis helps in providing an explanatory model about the illness (i.e., why an individual develops an illness at a particular point of time). It has implications in disease prevention by health education and generating awareness. Many clinical diagnoses incorporate an etiological term in the diagnostic terminology used. For example, acute viral encephalitis diagnosis indicates that the etiology of the medical condition is “viral infection.” Similarly, metabolic encephalopathy diagnosis indicates the etiology to be “metabolic imbalance.” The diagnosis, post-traumatic stress disorder, indicates to the underlying etiology “stress-related trauma.” Certain etiological agents have been named after the clinical diagnoses (e.g., *Salmonella typhi* after the name typhoid fever; *Vibrio cholerae* after the name cholera). Understanding etiology is important from the perspective of prevention. The preventive strategies are determined by the underlying etiology. For example, prevention of HIV infection is carried out through understanding the etiopathogenesis of HIV infection/AIDS (through the knowledge of modes of transmission, course and outcome of illness, risk factors).

Understanding etiology in the context of psychiatric disorders is important and has various

clinical implications. Psychiatric disorders are the resultant of complex interaction of multiple etiological factors (Langguth et al. 2009). The causes of a particular psychiatric condition may be different in different individuals. For example, the etiology of depression may be mostly biological in an individual (who has positive family history and past history of depression) whereas predominantly psychosocial in another individual (who had a recent significant life stressor). Various models (essentialist kinds, socially constructed kinds, practical kinds, mechanistic property cluster kinds) attempted to explain psychiatric disorders, of which the mechanistic property cluster kinds explain psychiatric disorders by linking them with their potential etiologies (causal mechanisms), hence becomes the most accepted model (Kendler et al. 2011).

Conclusion

Etiology is the first stepping-stone in the journey to understand an illness. The significance of understanding the etiology is enormous as it helps in classifying illnesses, directing assessments (investigations), as well as formulating the management plan. Understanding of illness or disease remains incomplete without the knowledge of etiology.

Definition

The term *eugenics* refers to both intellectual and political efforts at altering human heredity for the purpose of (1) decreasing the level and prevalence of perceived socially *undesirable* traits in a population (negative eugenics), especially if the rising level and prevalence of such traits are understood as effects of certain kinds of genetic change in a population (termed *dysgenics*), and/or (2) increasing the level and prevalence of perceived socially desirable traits in a population (positive eugenics).

Introduction

In 1883, *Sir Francis Galton* combined the prefix *eu*, meaning *good* or *well*, with *genic* or *genos* meaning *kin* or *stock*, to create the novel term *eugenics*. *Eugenics* thereafter became a science of particular import and a movement of deep controversy. What could be termed *folk eugenic*

thinking can however be traced back to the writings of classical philosophers, most notably Plato in his *Republic*. Charles Darwin's *On the Origin of Species* and Francis Galton's *Hereditary Genius* provided the scientific basis on which the biological theory and the applied science of eugenics were based (Hertler 2014). As an academic field, eugenics involved study of intelligence, character, and health, and indeed its pursuit early in the twentieth century spurred many significant developments in psychometrics, anthropometrics, and statistics. In its policy applications, eugenics was an attempt to replace “natural” with “artificial” forms of selection, such as selective breeding. More recent incarnations of eugenic thinking advocate for the restriction of artificial selection to prenatal interventions via the use of *reprogenetic* technologies, such as embryo and gene selection.

Review

Ideology

Applying the adjective *utopian* to eugenics might seem incongruous, but eugenics was in fact a utopian ideology. As with other ideologies, laudable ends were sometimes used to justify deplorable means (Chesterton 2000; Kevles 1998). Drawing still further parallels with other utopian, specifically *collectivist* movements, the eugenics movement advocated the top-down control of what had once been regulated by bottom-up forces. For eugenicists, the factor of interest was population quality; for communists, economy; for French revolutionaries, fraternity; for German national socialists, racial purity. Nevertheless, the utopian qualities of eugenics were idiosyncratic and limited, and so eugenics was “utopian” in a qualified sense. That is partly because eugenics as a movement was an outgrowth of eugenics as a science. Secondly, even while many a eugenicist fancied progressive visions of human enhancement, demographic anxiety was the movement's wellspring. Through the latter, eugenicists shared a deep pessimism with intersecting ideologies originating in a

nineteenth-century European culture looking downward from its zenith.

Eugenicists and *Malthusians* interfaced, as their overlapping ideologies would predict (Woodley of Menie et al. 2017). Both intellectual currents involved elites wary of the reproductive success of lower echelons of society, and both feared demographic futures characterized by degeneration and civilizational collapse. Nonetheless, eugenicists and Malthusians had different demographic concerns, the former concerned about the *quality* and the latter the *quantity* of populations, as C.V. Drysdale recognized (Klausen and Bashford 2010). In reality, it seems that both worries were often found in the same people. Consequently, at least by the 1930s, the two groups were more likely to attend the same conferences and collaborate on joint ventures than they were to argue and undermine one another (Klausen and Bashford 2010). Indeed, the interwar period resulted in the following mutual goal, detailed by Soloway (1990, p. 102): “Together [these movements] held out the promise of the intelligent control of the reproduction of the lowest classes and the promotion of more births among the ‘social units that are generally *most fit*.’”

Historicity

Soloway (1990, p. xxii) notes the following:

It is not clear to what extent the unsavory association of eugenics with Nazism, racism, and anti-socialist, pro-capitalistic class prejudices made it an unattractive subject after the war for scholarly inquiry by historians of science as well as of the social and intellectual history of modern Britain.

Consistent with Soloway’s observation, histories of eugenics are in short supply. To make matters worse, many of those that are available treat the subject with insufficient scholarly care and sophistication. This substandard academic work is frequently the fault of historians’ rush to repudiate supposed evils of the past, as Soloway’s remark above intimates.

As reviewed by Woodley of Menie et al. (2017), and also by Soloway (1990), eugenics is inaccurately viewed as an artifact of the hard right. One is made to think of libertarians, fiscal conservatives, and other elitists steeped in Social

Darwinism when reading cursory treatments of the eugenics movement. And indeed it was not unheard of for elitists and conservatives to become partisans of eugenics. On the other hand, there were extreme leftists who no less vehemently than rightists affirmed eugenic doctrines, including liberal progressives such as Sidney Webb, L.T. Hobhouse, and J.A. Hobson (Soloway 1990). In fact the communists Lenin and Trotsky both endorsed eugenic practices (Adams 1989). This may come as a surprise to modern readers but only because of the tendency to erroneously project the contemporary nexus of science and politics into the past. It was not always believed that biological explanations of social problems, e.g., crime, poverty, and inequality, ran afoul of progressives’ melioristic politics. This is partly due to the fact that what Galton called the *nature/nurture question* was a matter of some controversy among early eugenicists. Specifically, though evolution was accepted fact among eugenicists, there remained many Lamarckians among the Darwinian eugenicists; and given that Lamarckian evolutionary theory entails that hereditary stock can be altered by environmental means, progressivist meliorism was compatible with Lamarckian construals of eugenics. So a Lamarckian eugenicist could believe that the best way to improve the hereditary quality of a population is to improve the environments to which “the unfit” are exposed, rather than discourage their reproduction (though Lamarckian theory would admit of that solution too). Thus the comingling of Lamarckians and Darwinians necessitated a distinction between *natural eugenics* and *nurtural eugenics*, the former being improvement of a population’s heredity by way of breeding and the latter being such improvement by way of environmental change. It goes without saying, however, that any notion of nurtural eugenics declined along with Lamarckianism.

In addition to being bipartisan, the eugenics movement was cosmopolitan (Currell 2010). It originated in England, founded upon Galton’s work, but was thereafter imported to the United States, Italy (Cassata 2011), Spain (Cleminson 2000), Greece (Trubeta 2007), and Sweden

(Spektorowski and Mizrachi 2004). It was embraced in South America (Harris 1922), especially within interbreeding, multiethnic Brazil (Hochman et al. 2010). Eugenic science and policy thereafter diffused eastward, finding favor in Russia (Adams 1989), Japan (Otsubo and Bartholomew 1998), China (Pearson 1995), and portions of South East Asia (Amrith 2010). Within countries, not all were converts, but eugenics is described by some as having grassroots support, even while it brought social elites within its orbit, including Leonard Darwin, Winston Churchill, Alexander Graham Bell, Thomas Hunt Morgan, George Bernard Shaw, H.G. Wells, and Theodore Roosevelt (Hertler 2014). Therefore, far from being unique to Teutonic racialism or some other brand of European rightism, the eugenics movement straddled not just the right and left but also the Occident and Orient and upper and lower social strata.

Application

Eugenic policy varied in terms of private as opposed to state support and assumed different characteristics depending on its sponsoring regime and the nature of its population (Hertler 2014). Eugenic policies typically targeted procreation in efforts to prevent the existence of “the unfit,” though in rare cases eugenics could turn homicidal, aimed at destroying those who supposedly threatened to spread socially undesirable traits to future generations. But the most fundamental and critical distinction to be made with respect to eugenic policy is between *positive* and *negative* eugenics. Positive eugenics promotes the reproduction of the “fit”; negative eugenics opposes the reproduction of the “unfit.” A second distinction centers on whether eugenic policy is advocated or compelled; in other words, it matters greatly whether eugenicists merely encourage the voluntary adoption of eugenic practices or whether they seek to coercively realize eugenic aims through governmental or other means. Applications of eugenics have varied across time and space, covering the spectrum from advocacy to coercion. For instance, British eugenics programs were quite benign, e.g., they promoted early marriage for the intelligent and

capable, while German National Socialism used force in the pursuit of eugenic goals (Black 2003). The United States perhaps occupied an intermediate position, as it attempted to proselytize the uninitiated while maintaining an active sterilization program that was countenanced by the majority of states (Lombardo 2008).

Repudiation

Eugenic views found favor in various ideologies of the interwar period: socialism, communism (Adams 1989), nationalism (Quine 2010), gilded-age individualism, libertarianism, and laissez-faire economics (Hofstadter 1992) (see Woodley of Menie et al. 2017). Nevertheless, it is important to note that the last three ideological strains really exhibited *Social Darwinism* rather than straightforward eugenics as embodied in the *First-Wave Eugenics Movement*. Social Darwinism sought to achieve eugenical outcomes via *benign neglect*, i.e., the withholding of welfare and other state-based forms of social support from the lower classes with the intention of encouraging their members to live (and procreate) within their limited means. Conversely, the First-Wave Eugenics Movement, emanating most directly from the work of Francis Galton and achieving its greatest influence early in the twentieth century (prior to World War II), sought to enhance the hereditary quality of populations by directly intervening in the reproductive affairs of individuals. While both the First-Wave Eugenics Movement and Social Darwinism collapsed by the mid-twentieth century, the focus here is specifically on the former. On the matter of the First-Wave Eugenics Movement’s breakdown, a number of factors ought to be considered.

There are, first, indirect factors that undermined the First-Wave Eugenics Movement. Among these is the loss of strong national identities in the wake of globalization, a process that became especially pronounced after World War II, in that the Allied Powers sought to avoid another devastating worldwide conflict through a number of policies promoting the economic integration of nations (Westbrook 2004). To the extent that globalization superseded nationalism, the broad base of support for applications of eugenics aimed at

increasing the competitiveness of nation states in particular was sure to erode. Another, and often overlooked, indirect factor weakening the First-Wave Eugenics Movement was the definitive repudiation of *Lamarckian evolution*. Lamarckian evolution, synonymous with the *inheritance of acquired characteristics*, was, as previously mentioned, what largely enabled the embrace of eugenics on the left, which generally subscribed to environmental determinist views of human nature. Once Lamarckian evolution was discredited, it became more difficult to justify adherence to eugenics within the ideological frameworks of leftism. Although these and other indirect effects were important, direct effects likely had a greater role in undoing the First-Wave Eugenics Movement. Specifically, First-Wave eugenic policies drew fierce criticism that tarnished the movement's image.

In the early to mid-twentieth century, sterilization was a common eugenic practice (Hertler 2014). For example, nearly 8000 American citizens were sterilized in approximately 50 years of North Carolina history. Like other states, North Carolina had eugenic laws and a eugenics board. Whereas some states officially sanctioned sterilization, others tolerated its discretionary use by local physicians. California and Virginia rivaled North Carolina in the number ultimately sterilized. To these, Washington, Vermont, Utah, South Dakota, Pennsylvania, and South Carolina were added as states that sanctioned sterilization but practiced it on a smaller scale. Federally, sterilization was upheld as a constitutional practice by Supreme Court Justice Oliver Wendell Holmes. Nevertheless, such coercive negative eugenic practices invited a backlash, as it was and is thought that these involved extensive violations of human rights.

Several other factors contributed to the demise of the First-Wave Eugenics Movement. First, Soviet agronomist Trofim D. Lysenko "reimagined" heredity and evolution in line with Stalinist interpretations of dialectical materialism. In doing this, he sought to both "de-privilege" the gene as the sole vehicle of heredity and revive Lamarckian theories of the inheritance of acquired characteristics. The introduction of Lysenkoism may have given leftist academics an intellectual

basis on which to reject eugenics, which they may have been inclined to do in light of the latter's previously discussed "natural" turn. Unlike earlier Lamarckian eugenicists, Lysenkoists' interpretation of heredity was so radically at odds with standard Darwinian theory, e.g., maintaining that environment is part of heredity insofar as the former enters into "dialectical correspondence" with organisms, and so politically charged that their relation to anything derived from Darwinian thinking, such as Galtonian eugenics, was purely acrimonious. Second, a new school of anthropology, spearheaded by Franz Boas and his students, was instrumental in advancing environmentalist views of human nature to the detriment of the hereditarian doctrines on which mature First-Wave eugenics relied. Third, the eugenic research, policy-making, and theorizing of the interwar period were disrupted by World War II. Fourth, evidence was starting to accumulate that the theoretical bases of the First-Wave Eugenics Movement were seemingly false. Alarmist predictions of dysgenic decay in national intelligence, made in the interwar years, were not observed when eugenicists conducted follow-up studies comparing the performance of older and newer cohorts on intelligence tests (Cattell 1950). On the contrary, comparisons of the IQ scores of cohorts suggested that intelligence had increased over time – eugenicists were therefore among the first to accidentally find what is today called the *Flynn effect* (though the inference that dysgenic decline was not in fact occurring is likely false; see Woodley of Menie et al. 2017). Finally, New Left historical revisionism in the 1960s cast eugenics in a negative light. Rather than discuss the progressivist or even utopian cosmopolitan aspects of First-Wave eugenics, these historians argued that eugenic thought intrinsically favors programs of genocidal racial hygiene of the sort pursued by German National Socialists against Jews and other minority groups (Glad 2011).

Eugenics Behind the Natal Barrier

Active state-sponsored eugenical programs are now historical relics, commonly deplored and sincerely regretted. Chastened by the debacles and misdeeds of the past, and softened by humanistic sentiments, few would now endorse top-down

control of human breeding to prevent disadvantaged, poor, physically disabled, and/or mentally ill individuals from reproducing. Still, this does not mean that humankind is fully opposed to eugenics. It must be stressed that certain eugenic practices are in fact broadly acceptable and legally sanctioned, as long as they are voluntarily adopted by and for particular persons (or their unborn or perhaps very young children) rather than coercively imposed by others or the state.

Support for these autonomous reproductive decisions is properly recognized as the basis of the *Second-Wave Eugenics Movement*, starting around 1990 and continuing to the present. This extends beyond selective abortion and implantation to more intricate applied biotechnologies that are alternatives to rights-infringing procedures, such as forced sterilization.

Stock (2002), like Habermas (2000), relates the bioethical and broader philosophical complexities of genetic intervention. Though some are cautious and skeptical in light of the difficulty of these matters, others argue that the application of biotechnology to eugenic ends is inevitable, with the only questions being *when*, *where*, and *how* (Habermas 2000; Stock 2002; Agar 2004; Salter 2015).

The individualistic character of the Second-Wave Eugenics Movement ought to be recognized as a major deviation from the First-Wave Eugenics Movement. Woodley and Figueredo (2013) analyzed the works of major First-Wave eugenicists and found that they sought to promote traits in populations that would redound to *group-level* fitness, especially high levels of intelligence, heroism, and altruism. Therefore Woodley and Figueredo (2013) defined eugenics as efforts to increase the frequency of traits in populations that augment group-level fitness, and to decrease the frequency of traits that have the opposite effect. By contrast and as previously indicated, Second-Wave eugenicists seem mainly interested in empowering *individuals* to autonomously enhance their well-being (Agar 2004), which will largely serve to improve *individual-level* fitness, perhaps at the expense of group-level fitness. The First-Wave Eugenics Movement was largely an extension of the moral spirit of its age, which promoted concern for the survival and flourishing

of populations above such concern for individuals; this collectivist moral orientation was likely a product of the group-selection regimes to which nineteenth- and, to a lesser extent, early twentieth-century European populations were subjected as a result of the severe intergroup competition to which they were exposed (Woodley of Menie et al. 2017). The Second-Wave Eugenics Movement is, correspondingly, of a piece with the hedonistic and self-interested morality that has been ascendant in Western nations since the 1960s at the latest, which is in turn an outgrowth of the individual-level selection regimes that Western populations have experienced following the virtual disappearance of intergroup competition and hence of group selection (Woodley of Menie et al. 2017). Though the individualistic nature of Second-Wave eugenics might give it a benign appearance, the risks that attend direct manipulation of human genomes should be considered.

Consider Paul and Moore (2010), who wrote of Galton:

He stood all but alone, lacking a scientific consensus to support his biological premises. Natural selection had few adherents, and many converts to evolution, still accepting Lamarckian inheritance, doubted selection's sufficiency. Worse, Galton had little basis for applying selection to humans. He lacked data on the inheritance of mental and moral traits for any population, and his pedigree research was restricted to eminent families.

Though primarily meant to chasten Galton and Galtonian eugenicists, the lesson might well be applied to all efforts to change human heredity that carry or may carry serious risks. Some argue that should eugenic technologies become widely available for elective use, they are likely only to reduce or perhaps eliminate deleterious genetic variation (e.g., by selecting against variants that cause schizophrenia), rather than inadvertently lower levels of desirable genetic diversity (Stock 2002). However, even after genetic variants have been more reliably linked to harmful traits and conditions, the relevant scientists might still not know enough to carry out genetic interventions without serious risks. For example, pleiotropy, or the influence of one gene on more than one phenotypic trait, is an aspect of human genetic architecture that currently presents a major obstacle to the

development of some “eugenic” technologies (e.g., genome editing). This is because altering pleiotropic genes to enhance one trait could damage one or more other traits. Nevertheless, there is no reason to believe that challenges of this sort are insurmountable, especially if geneticists and related scientists are able to conduct research on these problems free from efforts to stop their work stemming from anachronistic fears about eugenics.

Conclusion

Eugenics was more than anything else an attempt at artificial, top-down control of selection processes that had previously operated from the bottom up. In the nineteenth and early twentieth centuries, elites found themselves in a world radically transformed through the industrial revolution, a process that spurred unprecedented economic development and thereby profoundly reduced levels of morbidity and mortality that in previous centuries had constrained human population growth, particularly of those carrying traits deemed to be socially undesirable. They also saw the widespread utilization of contraceptives among those high in socially desirable traits, as well as the dysgenic consequences of the aristocide and extirpation of Western monarchies that characterized World War I. The reproductive advantage that went with power, wealth, and talent in Western European premodernity for centuries was suddenly attenuated. Eugenics was first and foremost a bid to forestall the adverse consequences anticipated to result from these “dysgenic” processes.

Grandparental care; Grandparental involvement;
Grandparental solicitude

Definition

The investment (e.g., time, emotional closeness, material resources) a grandparent allocates to a grandchild.

Introduction

The finding that parental solicitude is sex specific, with mothers investing more in their offspring than fathers (Daly and Wilson 1980), can be extended to grandparental solicitude. According to the life history theory, persons can maximize their reproductive success by parental effort, but also by their nepotistic effort (supporting persons with whom they share genes by common descent). Thus, grandparents can maximize their long-term reproductive success by allocating their grandparental effort discriminatively.

Preferential Grandparental Solicitude: Theory

Euler and Weitzel (1996) hypothesized that the amount of discriminative grandparental investment can be predicted by two sex-specific reproductive factors: (1) Because of their higher obligatory investment into each single reproduction, females could in the ancestral past best maximize their genetic replication by maximizing maternal care, whereas for human males with their high reproductive potential, the opportunity costs for parental investment were higher than for females. These costs reduced men's willingness to invest in their offspring. (2) Maternity is certain, whereas paternity may be uncertain. These two sex-specific conditions led to asymmetries which are also evident in grandparental investment into their adult children and their grandchildren. For grandparents, paternity uncertainty, here better named relationship uncertainty, may enter twice. The maternal grandmothers can be certain about her own as well as her daughter's maternity. The paternal grandfather, however, suffers paternity

uncertainty twice. He can neither be certain that his son is his biological offspring nor that the children of his son are his son's biological offspring. The other two grandparent types, the maternal grandfather and the paternal grandmother, each have one link of paternity uncertainty. Combining both sex-specific reproductive factors, a rank order of grandparental investment was predicted: Most investment can be expected by the maternal grandmother, followed by the maternal grandfather, the paternal grandmother, and the paternal grandfather.

Preferential Grandparental Solicitude: Original Data

In the Euler and Weitzel (1996) study, a convenience sample of both student and community participants (aged 16–80 years) was asked by a questionnaire how much each grandparent had cared for them (“gekümmert”) up to the age of 7 years. The German verb “kümmern” has both a behavioral and a cognitive–emotional meaning, namely, to care for, to look after, and to be emotionally and/or cognitively concerned about. From the total sample of 1,857 respondents, a subset of 603 cases were selected for analysis whose four grandparents were all still alive when the participant was 7 years old. This selection was made because due to females' higher life expectancy and the average age differences in reproductive partnerships, the maternal grandmother is the grandparent most likely to be still alive and the paternal grandfather least likely. The expected rank order of grandparent categories was obtained.

As expected, the intra-couple correlations for the grandparental solicitude ratings were high, pointing to the possibility that grandfathers comply with their spouses due to mating effort. Therefore, the order and solicitude ratings differed for grandparents living separately except for the maternal grandmother. The solicitude ratings for the grandfathers living separately from their spouse, however, dropped considerably such that

the paternal grandmothers now cared more for her grandoffspring than the paternal grandfathers, and the care showed by paternal grandfathers was extremely low. As opposed to separation, widowhood had no effect on the amount of grandparental care.

Residential distance is a strong determinant for grandparental solicitude, but the residential distances for the four grandparent types did not differ significantly. The residential distance had tendentially the least impact on care shown by the maternal grandmother.

The sex of the grandoffspring had a small effect on the reported grandparental care, with women reporting having received more care than men. Variables which did not affect grandparental solicitude were grandparental age, number of grandparents still alive, and socioeconomic status (Trivers–Willard effect).

Replications and Generalizations of Original Findings

Subsequent studies have replicated this finding (for summaries, see Coall and Hertwig 2010; Euler 2011) for a variety of indicators or proxies of investment, for example, contact measures (e.g., frequency, duration), grandparental adoptions of grandchildren, ratings of emotional closeness, mourning upon the death of a grandchild, terms of verbal address (diminutive and endearing name most often for the maternal grandmother), naming favorite grandparents, and most recently positive attitudes toward retirement during transition to grandparenthood (Wiese et al. 2016).

Sex-Chromosome Relatedness

The relatedness between grandparents and grandoffspring described at the outset applies only to autosomal genes. The sex-chromosome relatedness, however, is different because males are heterozygous (XY) with respect to the sex chromosome. The grandfather passes his

Y chromosome directly to his grandsons, whereas the X chromosome undergoes recombination. With respect to the Y chromosome, the paternal grandfather is thus 100 % related to his grandsons, but 0 % to his granddaughters. A hypothesis about preferential care of paternal grandfathers for their grandsons, however, could not be supported empirically (Chrastil et al. 2006).

Cultural Limitations

The obtained rank order of grandparents, from maternal grandmother to paternal grandfather, is not culturally universal. Most of the reported studies have been done in Western industrialized states and milieus. In traditional pastoral, expressedly patrilocal, or otherwise patrifocal societies or societal milieus, the paternal grandparent–grandchild relationships play a more important role than the maternal ones (Pashos 2000) and thus care more for grandchildren than do maternal grandparents.

Effects of Grandparental Investment on Grandchild Development

Does grandparental care, particularly the grandmaternal one, have an impact on the grandchild's development? Sear and Mace (2008) reviewed 45 studies about the presence of kin for child survival, most of them from natural fertility populations, and found that next to the mother, whose presence contributed to child survival in all studies, the maternal grandmother was the second most important kin. For industrialized Western societies, where child survival is asymptotically low, the question arises whether grandparental care makes positive contributions to the grandchild's development. Coall and Hertwig (2010) reviewed the evidence, unfortunately relatively sparse, and concluded that positive contributions by emotionally close grandparents are most likely for risk families (e.g., lack of social

support for the mother) or situations of duress, like maternal depression or drug misuse. Tanskanen and Danielsbakka (2012) reported evidence for an association between maternal, but not paternal, grandparents' involvement and fewer emotional and behavior problems in the grandchildren.

The Grandmother Hypothesis

The data about preferential grandparental care, particularly the generally prominent role of the maternal grandmother, lends support the so-called grandmother hypothesis, first stated by Williams (1957). According to this hypothesis, the relatively early menopause of human females, unequalled in other mammals, is an adaptation. Rather than to continue producing own children, a middle-aged woman gains more fitness benefits by investing her effort into helping her daughter raising the grandchildren. Whether the menopause is indeed an adaptation in its own right, however, remains a matter of debate (see Euler 2011).

Conclusion

The study by Euler and Weitzel (1996) was the first one to show that in the sample studied, grandparental solicitude as a proxy for grandparental investment differed systematically between the four different types of grandparents and that this preferential solicitude could be predicted by evolutionary theory.

Definition

Eusociality is an elaborate form of social organization, involving a reproductive division of labor among members, overlapping generations, and cooperative care of the young.

Introduction

Eusociality is thought to have evolved as a group-living strategy where group mates were relatives and ecological conditions made it difficult to reproduce personally because of high predation risk and high rates of failure in founding new nest. It has evolved independently and separately in different taxonomic groups.

What Eusociality Is

Eusociality is an elaborate form of social behavior, where some individuals in the group (usually

called “colony”) do not reproduce for the benefit of others. Thus, a reproductive division of labor exists. Two or more overlapping generations coexist in eusocial colonies – typically, parents and their offspring – and they cooperate in caring for the young (Wilson 1971). Nonreproductive individuals – which, in some cases, are irreversibly sterile – forgo reproduction and accomplish different tasks such as foraging, colony maintenance, and defense, basically helping in raising the offspring of the breeders (Wilson 1971). Typically, there are castes in eusocial societies, that is, groups of individuals which are behaviorally specialized for a social task (in Crespi and Yanega’s (1995) view, eusociality should be limited to those social organizations where caste specialization is irreversible).

Social insects are typical examples of eusocial animals (Wilson 1971). In honeybees and ants, for example, the colony is composed of one or more egg-laying “queens” and up to thousands (even millions) sterile females (“workers”) which spend their lives helping the queen (or the queens) to raise her young. Generally, workers are queen daughters, which do not abandon the natal colony when they become adults. In some eusocial species, queens and workers differ not only physiologically and behaviorally from each other but also morphologically (i.e., phenotypic castes exist), and all individuals have irreversible roles; therefore, they cannot switch from the worker to the reproductive caste or vice versa. In some ants and higher termites, multiple, morphologically distinct, sterile castes exist, which are specialized on particular social roles within the colony, e.g., foraging or colony defense (Hölldobler and Wilson 1990). For example, in turtle ants (*Cephalotes* spp.) a soldier caste is specialized on blocking cavity entrances with their armored heads, which fit well the size and shape of nest entrances (Powell 2008). In the neotropical termite *Neocapritermes taracua*, workers have explosive “backpacks”; they burst and release a toxic sticky fluid when they are seized by enemies, such as other termites (Šobotník et al. 2012).

Eusociality is not limited to social insects. Recently, it has been reported in a few species of echinostomoid trematodes, or fluke worms. These worms are parasites and have complex life cycles involving several developmental stages occurring in different hosts. Once the founder larva infects its first intermediate host – typically, a snail – it initiates reproducing clonally, thus giving rise to a colony of genetically identical individuals living in the same host snail (Hechinger et al. 2011). Some worms develop a large size, whereas others stay relatively smaller. The large worms reproduce asexually in their turn giving rise to both large worms capable of reproducing and dispersing morphs (cercariae) which will leave the host snail and search for the next host, where they will complete their life cycle and reproduce sexually. The small worms do not reproduce at all; they spend their lives in the snail and physically fight parasites other than their clone mates when they encounter them throughout the snail body. By doing this, these worms behave as “soldiers” defending “their” snail – which is the living resource they get their living from – against competitors and thus help large worms to reproduce. In this way, they favor the spreading of copies of their genes in the next generation through the help they give to their clone mates (Garcia-Vedrenne et al. 2010; Lloyd and Poulin 2012).

Eusocial organization is not limited to invertebrates. Eusocial mole rats are small, African, sub-Saharan rodents which live in underground colonies of tens of individuals. A female (the queen) and one to three males reproduce and their offspring stay at the natal colony where they spend their lifetime digging foraging tunnels while searching for roots and tubers, maintaining the burrow and defending it against predators, such as snakes (Jarvis 1981; O’Riain and Faulkes 2008). Castes are not irreversible in this taxa: if the reproductive female dies, a female “worker” will rapidly develop a larger body size and will undertake the reproductive task. The same fate may occur to male “workers,” if one of the

reproductive males die. Because of low dispersal, individuals in the colony are usually relatives: parents and sons and daughters, cousins, aunt and uncles, etc. Eusocial mole rats typically live in arid habitats, where physical and climatic conditions are harsh: soil is hard to dig, air temperatures extreme, rain sporadic or unpredictable, and food scarce. These ecological factors may have played an important role in the evolution of mole-rat sociality, as stated by the aridity food distribution hypothesis (O’Riain and Faulkes 2008). Low success of dispersal from the natal nests (mainly limited to special morphs with large fat reserves than non-dispersers, O’Riain et al. 1996), the difficulty of digging a new burrow, and the difficulty of finding food may have favored (during evolution) individuals which stayed at the natal nests.

Eusociality: Occurrence

Eusociality is rare among animals but has evolved independently in different taxonomic groups. Besides mole rats and trematode worms, it has been reported in thrips, in sponge-dwelling shrimps, and in gall-forming aphids. In contrast, it is relatively common among hymenopteran insects (the taxon that includes ants, bees, wasps) and among termites. In order to understand the nature of eusociality, and the conditions which have favored its origin and evolution in different taxonomic groups, it is interesting to investigate which features the diverse eusocial taxa share.

Factors Favoring the Evolution of Eusociality: Genetic Factors

From an evolutionary point of view, eusociality is puzzling because it involves individuals which do not contribute their genes to the next generation through reproduction; nonetheless, helpers persist generation after generation. However, genetic relatedness between colony members offers a solution to the puzzle.

Natural selection favors those behavioral, physiological, morphological traits that increase the frequency of an individual’s genes in the next generation. Helpers are likely to increase the frequency of their own genes in the next generation if

the helpers and the breeders are likely to share identical genes by descent from a common ancestor. Typically, eusocial colonies consist of related individuals. Colonies are generally composed by a queen and their offspring or a pair of parents with their offspring; in other cases, colony members are clones (genetically identical individuals produced through asexual reproduction). For example, trematode colonies are composed of clones (genetically identical individual originated through asexual reproduction from a single “parental” individual which produces copies of itself); mole-rat colonies are sort of large families where colony members are relatives and mating between related individuals (i.e., inbreeding) is not rare (which further increases relatedness between colony members) (Reeve et al. 1990).

The observation that colonies of eusocial animals are generally composed of related members has been crucial to the understanding of the genetic background that has favored the evolution of eusociality, and the idea was originally formulated by W. D. Hamilton (1964) to account for the evolution of cooperation in social insects. In social insects, such as bees, ants, and wasps, colonies are generally composed of queens and their daughters, which help the queen to reproduce and care for their young sisters, which in turn will develop as workers and/or future queens. In Hymenoptera, genetic relatedness between sisters is especially high because these insects have a special mechanism of sex determination. Females originate from fertilized eggs (i.e., eggs fertilized by sperm), whereas males originate from unfertilized eggs. This means that males are haploid, i.e., they have a single copy of each chromosome – the only copy they received from their mother. In contrast, females have two copies of each chromosome, one inherited from their mother and the other inherited from their father. This mechanism of sex determination, which is called haplodiploidy, produces asymmetry in relatedness, simply because all sperms produced by a male contain the same copy of each chromosome – and, eventually, the same copy of each gene. This means that all sisters are genetically identical as for the genes they inherit from their father. Instead, the eggs produced by a queen (which has two copies of each chromosome and

thus two copies of each gene) contain either one or the other copy of each gene. This means that sisters have one probability out of two of inheriting the same gene from their mother. Sisters are therefore genetically identical as for their paternal genes and have one probability out of two of sharing a particular maternal gene. Therefore, haplodiploidy makes sisters genetically very close to each other (the likelihood of sharing a gene with their sisters is on average $r = 0.75$) and eventually closer to each other than to their brothers ($r = 0.25$), which may explain why sterile workers are females in social insects. In an evolutionary perspective, selection may favor either individuals that spread their genes to future generation through personal reproduction – as queens do, obtaining direct fitness benefits – or individuals which spread their genes to future generation via helping relatives to reproduce, as workers do, obtaining indirect fitness benefits. It comes from Darwin theory of evolution through natural selection (Darwin 1859) that traits which are heritable and enhance an individual reproductive success should increase their frequency across generations. The novelty of kin selection theory (or inclusive fitness theory) (Hamilton 1964) was to link the evolution of sociality in social insects with the observation that individuals can obtain a reproductive success either through personal reproduction or through reproduction of other individuals with which they share genes by common ancestry.

High relatedness between the helper and the recipient of the helping action is actually common among real eusocial insect colonies, but many exceptions exist. This is why many investigations have analyzed whether queens are monogamous (i.e., mated with only one male) or promiscuous (multiply mated). Indeed, relatedness between sisters decreases if the queen is multiply mated, which means that multiple patrilineal exist within the colony. Recently, the condition where queens mate with only one male has become one of the central focus of the analysis on the evolutionary origin of eusociality (Boomsma 2009, 2013). Monogamy is thought to be the ancestral mating system in taxa where eusociality with irreversible castes have evolved and multiple mating appears to be a trait evolved after sterile castes evolved (Hughes et al. 2008). Following Boomsma

(2013), irreversible castes have not evolved in vertebrates (such as mole rats) because vertebrates “were never monogamous enough.”

Factors Favoring the Evolution of Eusociality: Ecological Factors

Kin selection theory (Hamilton 1964) has provided a powerful explanation of cooperative parental care and worker sterility. However, ecological factors have played a crucial role in the evolution of eusociality. Generally, eusocial species live in habitats where living in group favors colony survival because it enhances the chances of finding food, defending and/or enlarging foraging territory against competitors, fighting back predators or parasites, etc. Indeed, mole rats live in extremely harsh environments, where founding new colonies is largely unsuccessful (e.g., disperser face starvation, O’Riain et al. 1996), and larger colonies are more likely to survive when conditions get even worse, such as during drought (Jarvis et al. 1988). More generally, whenever the nest is an easily defendable fortress, staying home and helping relatives to reproduce may be a valuable option to leaving and reproducing personally; similarly, if predation risk is high during foraging, group living individuals may gain a sort of life insurance because in case they were predated during foraging, their brood would be raised by their group mates (Queller and Strassmann 1998).

Are Humans Eusocial?

Recently, it has been argued that our species may fulfill the criteria for being classified as eusocial. Indeed, human societies have overlapping generations and cooperative care of the young and, in Foster and Ratnieks’ view (Foster and Ratnieks 2005), might also have a sterile caste. They reasoned that mid-age women become irreversibly sterile – menopause, a condition when they are physiologically incapable of reproducing – and usually help their close relatives. Although not occurring to young women, menopause is distinct from senescence (Hamilton 1966), and some hypotheses have been formulated to account for its evolution. One of them is the so-called grandmother-effect hypothesis that menopause in women may have been favored if aged women help their sons and daughters to

produce more grandchildren (which enhances the grandmother fitness through indirect reproduction) (Hamilton 1966). The grandmother-effect hypothesis is supported by a study documenting that the help of grandmothers significantly increased reproduction of close relatives in premodern populations (Lahdenperä et al. 2004). In this view, women in menopause may function as the sterile caste in human societies, getting fitness benefits through caring for grandchildren.

Conclusions

Ecological factors have favored group living in many species of animals, but among social animals, eusociality has rarely evolved, and it did so when high relatedness existed among group mates, at least ancestrally.

Evidence for Modularity

Breanna M. Wedde and J. Adam Randell
University of Central Oklahoma,
Edmond, OK, USA

Synonyms

[Mechanisms](#); [Psychological mechanisms](#);
[Specialization](#)

Definition

Modularity refers to that quality of any system wherein it consists of two or more functionally distinct mechanisms or components. In evolutionary psychology, modularity refers to this design feature in the human mind. Specifically, modularity refers to the various functionally distinct psychological mechanisms that comprise the human mind. These mechanisms are thought to serve evolutionary functions in that they address specific adaptive problems.

Introduction

Most aspects of modern design possess the quality of modularity. The cars we drive are modular in

that they have multiple mechanisms which perform distinct operations (e.g., radio, speakers, engine, carriage). Each of these modules is functionally distinct in that they each perform a distinct function. The radio receives radio waves and converts those radio waves into sonic oscillations emitted from another module: our cars' speakers. The engine (composed of several modules of its own) ignites liquid fuel, generating the kinetic force that propels the module in which we sit (i.e., the carriage) forward.

Many biological systems are also modular. Most animals' bodies are modular, in that they consist of multiple mechanisms, each of which is functionally distinct (e.g., heart, lungs, vascular system, etc.). Our hearts pump blood through our vascular system, while our lungs pull in oxygen to enrich that pumped blood.

Evolutionary psychology assumes that the human mind shares this modular design feature. Just as the modules of our bodies were shaped by evolution to solve the adaptive problems imposed by selection pressures, so too was the neural architecture of our minds shaped to solve adaptive problems.

The plethora of adaptive problems faced by our own species and our predecessors have generated a myriad of modules. These modules address adaptive problems ranging from disease avoidance to establishing and maintaining groups and communicating with those groups. In the following entry, we introduce some of the evidence for modularity. We begin, by exploring some of the more basic modules for processing kinship and indicators of disease. We then discuss models which scientists have proposed for understanding how these modules coordinate with one another.

Incest Avoidance and Kin Detection

Humans reproduce sexually. Sexual reproduction comes with many advantages. Species which reproduce sexually experience greater diversity than do species that reproduce asexually. This diversity allows sexually reproducing species to adapt to changes in their environments much quicker than can asexually reproducing species.

Further, any problematic mutations can be effectively removed from a sexually reproducing population much quicker than those same mutations could be removed from an asexually reproducing species.

However, many of these advantages of sexual reproduction are severely limited when individuals who share close genetic kinship reproduce. The genetic diversity of such a copulation is limited to that already present among the parents. Further, any mutations present in the parents would be sustained in the offspring (Lieberman et al. 2003). This creates the adaptive problem of incest aversion (Tooby and Cosmides 2005).

Building on Westermarck's (1891) proposal of an incest avoidance mechanism, Lieberman and colleagues (2003) proposed a kin detection module which would serve this incest avoidance mechanism in helping individuals solve the adaptive problem of incest aversion. Lieberman and colleagues suggested that this module would operate not only by identifying those with whom one has resided during early development (Westermarck 1891) but also by identifying those who have been cared for by one's own mother (i.e., maternal perinatal association or MPA).

Indeed, evidence confirms the operation of these modules. For instance, Lieberman and colleagues (2003) assessed how long participants reported to have lived with their siblings and the average extent of relatedness with their siblings. They then correlated these measures with how morally wrong participants found incest to be. The longer participants lived with their siblings, the more morally wrong they judged incest to be. Moreover, the more related participants felt they were to their siblings, the more morally wrong they judged incest to be.

Further, Lieberman, Tooby, and Cosmides (2007) found that participants use information about their own mother's caring for their siblings (i.e., MPA) more so than they used information about co-residence. Specifically, they found that co-residence information predicted incest aversion primarily when participants did not have information about maternal perinatal caring.

Others have replicated and extended these findings. Fessler and Navarrete (2004) found that

the longer people's history of co-residence, the greater their reactions of disgust and intolerance toward others' incest. However, this relationship was stronger in females than in males. Further, Luo (2011) replicated Lieberman and colleagues (2007) findings of MPA primacy (relying principally on MPA information when both MPA and co-residence information are available), but this primacy was greatest among men. That is, they found that women's aversion to incest with co-residing brothers was strong regardless of whether MPA information was present or absent. However, men's incest aversion only depended on co-residence when MPA information was absent (i.e., MPA primacy). Therefore, not only did Luo provide further evidences of Lieberman and colleagues' kin recognition module, but they extended it by replicating the finding revealing that females place relatively greater importance on co-residence than do men (Fessler and Navarrete 2004).

Pathogen Avoidance

Pathogens and parasites and other body invaders create a selection pressure, such that those with effective immune systems benefit, while those without effective immune systems suffer. This creates the adaptive problem of pathogen aversion. While our immune system is a clear line of defense against these invading agents of disease, Schaller (2006) has suggested that a psychological module, which he calls the behavioral immune system, developed as a first line of defense. Schaller argues that this module is sensitive to cues that indicate the presence of pathogens, parasites, and other health threats. The detection of these cues is thought to elicit cognitive (inferences of disease implying qualities) and emotional responses (disgust) that propel people away from these cues of disease.

The behavioral immune system has enjoyed a great deal of attention. This work has revealed that people react to cues of disease and illness, principally with avoidance. Those who live in pathogen-dense environments develop a suite of characteristics that motivate them to avoid new

experiences and unfamiliar people and remain close to known activities and people. For instance, those in pathogen-dense areas tend to be more collectivistic than individualistic (Fincher et al. 2008), religious, and family-focused (Fincher and Thornhill 2012) and less sexually promiscuous, less extroverted, and less open to new experiences (Schaller and Murray 2008). Further, greater feelings of disease vulnerability sensitize people to cues of disease, effectively lowering their criteria for detecting cues of disease (Miller and Maner 2012) and making them more likely to judge areas as crowded while also inclining them to avoid crowded places (Wang and Ackerman 2019).

Further, the pathogen aversion module is thought to be one of a cluster of several functionally similar modules sensitive to cues that indicate potential harm to the self. Researchers examining the behavioral immune system have found that the identification of certain threats to one's health in addition to pathogens can also trigger disgust, namely, sexual taboos and moral violations (Tybur et al. 2013). However, while cues of pathogen threat may be learned relatively early in life, the other behavior immune system modules may become sensitive to these other threats later in life (Oaten et al. 2009).

Modularity in Moral Foundations Theory

Building on our discussion of superordinate modules or clusters of modules, we now turn our attention to models which have been used as organizing frameworks for representing the coordination of multiple modules serving similar, though distinct functions. The first model we will discuss is that of moral foundations theory (Graham et al. 2013).

Moral foundations theory suggests that we rely on a set of moral intuitions (foundations) when making moral judgements (Graham et al. 2013). These moral foundations include the care/harm foundation, the fairness/cheating foundation, the loyalty/betrayal foundation, the authority/subversion foundation, and the sanctity/degradation foundation. Endorsement of these foundations

varies based on individual differences and cultural influences, but each foundation occurs cross-culturally (Graham et al. 2011). As with all modules, each foundation serves an evolutionary adaptive function.

These moral foundations can be grouped together as those serving an individuating function (operating for the benefit of individuals) or a binding function (operating for the benefit of the group; Graham et al. 2009). The individuating foundations of care/harm and fairness/cheating focus on interactions between individuals. The care/harm foundation addresses the adaptive problem imposed by the high investment necessary to rear children. Human children take an abnormal amount of nurturing before they can survive on their own. The care/harm foundation functions to promote caring and protecting children to ensure they survive to carry genes to their own offspring (Graham et al. 2013). This module may have been originally triggered by children in distress; however, the module may also generalize by reacting to signs of distress and suffering in adults, animals, and cartoons that resemble children. Reactions to these cues lead to outputs that work to ensure that people receive care until they can care for themselves. These outputs can include emotional reactions, such as compassion for the victim, anger toward perpetrators, and caring behaviors meant to relieve the distress.

The fairness/cheating module responds to the adaptive problem created by group living. Specifically, humans have had a better chance of surviving when they interact with one another, often by trading resources or services, while also avoiding free riders. The fairness/cheating foundation functions to promote the individual benefits of successfully navigating reciprocal relationships. This module may have originally been activated by either witnessing exchanges between people or hearing about an exchange from others; however, modern triggers also include inanimate objects involved in exchange, such as vending machines. Reactions to these inputs include emotion outputs thought to regulate future exchanges, such as anger and guilt in situations where an unfair exchange has occurred and gratitude when an exchange is fair.

Group living is not only transactive but also communal, creating additional adaptive problems. Being part of a cohesive group can increase chances of survival by providing access to shared resources and providing protection from other group members. The binding foundations of loyalty/betrayal, authority/subversion, and sanctity/degradation are modules focused on addressing the adaptive problems created by how people interact with one another within their groups.

Given the great advantages provided by communal group living, maintaining the cohesion of those groups becomes a selective pressure. The loyalty/betrayal module promotes formation and the maintenance of cohesive groups (Graham et al. 2013). This module responds to threat toward one's group cohesion (e.g., violating group norms). Reactions to these threats trigger behaviors meant to defend the cohesive elements of the group. These outputs include emotions such as group pride or anger toward perceived traitors.

Groups also tend to establish status hierarchies. Hierarchies provide a sense of order and organization within groups. If appropriate interactions occur between those of higher and lower status in a hierarchy, the group is more likely to work cohesively, and moving up within the hierarchy is more likely. This increases survival odds by ensuring the group is functioning efficiently to protect themselves, as well as providing those of higher status with resources. The authority/subversion module serves to promote positive interactions among members within a hierarchy (Graham et al. 2013). This module responds to violations of these status hierarchies. Modern triggers include status dismissing interactions between employees and employers, law enforcement officials and non-law enforcement officials, and among people of different military ranks. Reactions to these status violations include emotional reactions such as respect and fear for authority, which reinforces separating people of different levels within a hierarchy.

Finally, communal group living can increase the chances of exposure to health threats, triggering concern with pathogen exposure and self-

harm as discussed above. The sanctity/degradation module is largely analogous to the behavioral immune system cluster of modules and thought to help people to avoid communicable diseases (Graham et al. 2013). In addition to those triggers mentioned above, modern triggers of this module include immigration, as those coming from another country may carry diseases, and sexual deviancy, which would increase the chances of the persons involved getting a sexually transmitted infection. In general, these modules involve the reaction of disgust and lead to harsher moral judgments. For example, exposing participants to disgusting stimuli which can signal the presence of pathogens (bad smells, a messy room, or gross video) leads them to make harsher moral judgments, particularly of moral violations related to the sanctity/degradation foundation (incest, sexual deviancy, cannibalism; Schnall et al. 2008).

Each of these moral foundations acts as modules within a moral framework described in moral foundations theory. Each module/foundation functions by attending to cues of various adaptive challenges and eliciting emotional and cognitive reactions that drive behaviors that aid survival of individuals and the groups in which they live. These modules trigger reactions to issues that are experienced as moral issues. Interestingly, those groups that place greater value on group cohesion experience the issues to which the binding modules/foundations respond as moral issues more so than do those groups that place less value on group cohesion (Haidt et al. 1993).

Modularity in the Fundamental Motives Model

Moral foundations theory organizes modules related to issues experienced as moral into an organizing framework. However, the fundamental motives model is a bit more ambitious. It attempts to provide an organizing framework for modules used across most if not all functional domains. The fundamental motives model suggests that psychological modules are organized by the motive these modules serve (Kenrick et al.

2010a). It builds on Maslow's hierarchy of needs by replacing Maslow's need for self-actualization with domains inspired by evolutionary theory, pertaining directly to successful reproduction. The resulting model identifies seven functional domains in which modules may be organized: immediate physiological needs, self-protection, affiliation, esteem/status, mate acquisition, mate maintenance, and parenting.

The physiological motive and the self-protection motives and their related modules are directly related to survival. The physiological motive consists of modules that produce behaviors that satisfy physiological needs (Kenrick et al. 2010a). The modules serving this motive convert inputs such as images (e.g., appealing foods), smells, and physiological imbalances (e.g., blood sugar levels) into behaviors which can reduce or remove these cues, such as hunger, thirst, and warmth-seeking. The self-protection motive consists of modules that address threats to, and ensure, safety. Inputs to these self-protection modules (e.g., angry male faces, darkness, and others with physical abnormalities or diseases) lead to emotional outputs such as fear and apprehension (Kenrick et al. 2010b). These emotional outputs subsequently prevent one from engaging with those who could potentially pose a threat, increasing safety.

Indirectly related to survival are the affiliation motive and the esteem/status motive, which are related to interpersonal behavior. The affiliation motive consists of modules which address the cohesive/belonging aspects of group living (Kenrick et al. 2010a) such as sharing resources, knowledge, and chores to increase survival. These modules react to cues of acceptance and rejection with behaviors designed to assess, prevent, and reestablish belonging. The esteem/status motive consists of modules that address resource acquisition, alliance formation, and status striving. These modules react to cues of achievement and competition, with behaviors aimed to successfully navigate status hierarchies (e.g., aggression; Griskevicius et al. 2009).

The remaining fundamental motives involve modules that address the various challenges of successful reproduction. The mate acquisition motive involves modules which respond to cues

of sexual receptivity with behaviors that lead one to seek desired mates (estimates of romantic interest; Perilloux et al. 2012; Sundie et al. 2011) and engage in behaviors to attract a potential mate (Kenrick et al. 2010a). Mate retention motivates those modules that help people to maintain long-term alliances with their mates (Kenrick et al. 2010a). These modules respond to threats of relationship dissolution and attractive alternative mates with reactions that insulate existing relationships, such as biasing evaluations of romantic alternatives (Maner et al. 2008). The parenting fundamental motive involves those modules that address the adaptive problem of offspring survival. Caring for children often includes sharing an abundance of resources with them, even if they are unable to contribute themselves. Parents who are more alert to children in distress will have a better chance of preventing accidents that could be life-threatening for the children. These modules respond to cues of offspring needs and threats to offspring safety with mechanisms that drive parents to be caring and generous toward their children and vigilant to distress.

Conclusion

In the preceding entry, we have discussed some of the evidence of modularity in psychological mechanisms. We have discussed some of the more basic modules such as kin recognition, incest aversion, and pathogen aversion, as well as some of the more global organizational frameworks which reflect the functional similarities in the more specific modules. However, regardless of the level of specificity, these modules and the more global frameworks for organizing them reflect the basic assumption of evolutionary psychology, that is, the human mind is modular in its design just as the rest of the human organism is modular in its design.

Definition

Evidence of brain modularity is the empirical body of findings that demonstrates that the brain

is organized into semiautonomous groups of neurons and brain regions that interact with one another through relatively sparse and long-distance pathways in the brain.

Introduction

Before there were brains, there was modularity. Modularity describes the extent to which a system has components that connect to or interact with other components, each of which is independent and functionally specialized. An example of a modular system is an electric circuit board made of connected electric components. Each component of the circuit board is an autonomous module with a specific independent function, connected to other modules with similar or different functions. Biological modularity, like artificial modularity, provides the organism with robust and specialized functions. These functions can independently evolve, develop, and respond to change. From this perspective, it is unsurprising that modularity is ubiquitous across biological systems (Scholsser and Wagner 2004).

The human body comprises various modular systems such as the cardiovascular system, the respiratory system, the digestive and excretory system, the visual system, the auditory system, and the nervous system. Each system has organs that constitute system modules that work together to support the smooth functioning of the system and organism in its entirety. In the human nervous system, the visual system's main organs, the eyes, communicate with the brain to interpret light waves as images. The inner and outer ear in the auditory system communicate via the brain to help us hear sounds of varying frequencies, such as a high-pitched sound of a chalk screeching on the blackboard or a low-pitched sound of distant thunder. More generally, the nervous system is composed of the central nervous system (brain and spinal cord) and the peripheral nervous system. Within the central nervous system, the spinal cord of vertebrates is a modular system with many ganglia. The brain is the "master ganglion" in vertebrates, and within the brain, there are numerous modularized systems.

Modularity in the Brain

A new branch of neuroscience called "network neuroscience" (Bassett and Sporns 2017) uses computational approaches based in graph theory to describe the organization of anatomical and functional brain networks at different spatial and temporal resolution scales (Betzel and Bassett 2016). A brain network can be depicted mathematically as a graph $G = \{N, E\}$, where N is a set of nodes (such as neurons or brain regions) and E is a set of edges (such as dendritic or axonal connections) connecting pairs of nodes. Statistics developed in graph theory allow us to compute network properties over G to make statements about the organization and roles of nodes, edges, or indeed the entire network.

The edges (region-region relationships) in a brain network are typically defined by three types of connectivity: anatomical connectivity, functional connectivity, or effective connectivity (Park and Friston 2013). Anatomical connectivity refers to anatomical connections among regions or neurons in the brain. At a low level of organization, anatomical connectivity can be detected using labeled tracer injections (Gamanut et al. 2017). In humans, anatomical connectivity can be computed from diffusion imaging data that represents white-matter pathways among regions in the brain. In contrast, functional connectivity at a high level of organization is often computed from the pairwise relationships between nodes via signals of BOLD-fMRI or electroencephalography (EEG)/magnetoencephalography (MEG). BOLD-fMRI signal can be obtained by scanning in the MRI scanner. The EEG/MEG signals can be recorded via multichannel recording using a group of electrodes centered over distinct regions of the brain. At a high level of organization, entire functional and anatomical networks can be mapped in the human brain, forming human "connectomes" (Sporns et al. 2005).

Functional networks are assembled from estimates of statistical dependencies between neuronal or regional time series data. Specifically, functional connectivity is often defined by the correlation, coherence, mutual information, or other measures of associations between time

series across nodes. Functional connectivity does not give information about causality or directionality. In contrast, effective connectivity is estimated from the lagged relationships between nodal activity in BOLD-fMRI and EEG/MEG signals. It is sometimes interpreted to represent the potential influence one neural system exerts over another at the synaptic or cortical level. Effective connectivity can evaluate directed relationships between regions as it is estimated with models with lagged parameters (e.g., vector autoregression, Granger causality, structural equation modeling, or unified structural equation modeling) or with a model of physiological dynamics (e.g., dynamic causal modeling).

Once a graph is constructed that represents a network, statistical diagnostics can be used to describe the organization of functional or anatomical connections in the brain from local to global scales (Rubinov and Sporns 2010). “Mesoscale” diagnostics are those that describe the organization of the network in between these two scales. Modularity is a mesoscale property of a network: modularity describes the organization of nodes into groups based on their connection to one another within the brain. A network is modular when sets of nodes form densely interconnected groups with sparser connectivity between groups relative to a null expectation (Newman 2006) (Fig. 1).

While specific definitions of modularity vary, one popular mathematical expression is defined by Newman and Girvan (2004). Consider an undirected graph with adjacency matrix A_{ij} and a partition of this graph into clusters or modules defined by $\{c_i\}$, where c_i describes which module node i belongs to; Newman and Girvan’s modularity Q is defined as:

$$Q = \frac{1}{2m} \sum_{i,j} \left(A_{ij} - \frac{k_i k_j}{2m} \right) \delta(c_i, c_j),$$

where $k_i = \sum_j A_{ij}$ is the degree of each node, $m = \frac{1}{2} \sum_i k_i = \frac{1}{2} \sum_{i,j} A_{ij}$ is the total number of edges, and $\delta(c_i, c_j)$ is defined as- $\delta(c_i, c_j) = 1$; if nodes i and j belong to the same module, $\delta(c_i, c_j) = 0$; otherwise.

Conceptually, Newman’s modularity compares the fraction of within-module edges in the graph to the expected fraction of within-module edges in a random graph with the same degree sequence as given by the configuration model. The randomization of edges is done to preserve the degree of each node for use as a null model that defines the expectation for Q under a random network of the same degree as the original network.

The value of Q is normalized such that it always lies in the interval $(-1, 1)$. The value of

Evidence of Brain Modularity, Fig. 1 What does modularity look like? (a) In principle, modularity is the extent to which nodes (gray circles) are grouped into discrete communities (nodes grouped into communities schematically represented by different colored backgrounds) based on the pattern of connections among nodes. Communities may have different sizes and configurations of within- and between-module connectivity. (b) An example connectivity matrix (“graph”) constructed from anatomical diffusion imaging data from one healthy individual. Each row and

column represents an “edge” – here, the number of estimated white-matter connections between a pair of regions. The highlighted squares along the matrix diagonal are those identified to be a module using a *community detection* algorithm. The off-diagonal rectangles are therefore the connections between modules. (c) These modules can be mapped back into a brain volume. Here, different communities are represented in different colors on a brain surface

Q depends on the partition resulting from a stochastic algorithm. Different methods for community detection have been developed to search for the partition of the graph that will maximize Q . Regardless of the specific algorithm, Q is a property of the partitioned graph and is considered a measure of modularity.

The notion of a “hub” is a key concept to understand the links within and between modules. Highly connected nodes in the brain may form links to multiple communities and are called connector hubs, which are more likely to be in the medial portions of the brain (Sporns et al. 2007). Connectors play important roles in intermodular communication. Regions that maintain relatively high connections within their own community form provincial hubs (Sporns et al. 2007; See Fig. 2). Hubs are thought to serve key roles governing organization within and between brain network modules by regulating intra- and intermodular information flow (Van den Heuvel and Sporns 2013).

Evidence of Brain Modularity (Functional and Anatomical Connections)

Evidence of brain modularity is widely observed both in anatomical and functional brain networks. Modules can allow rapid and efficient sharing of information among brain regions that tend to contribute to a common set of tasks or responses while promoting their functional specialization by creating boundaries that restrict the spread of

information across the entire network. Anatomical networks are more stable on shorter timescales relative to functional networks. Functional networks can be highly variable, exhibiting spontaneous dynamic changes during rest as well as characteristic modulations in different task conditions (Eickhoff et al. 2011). Some major common findings have emerged regarding anatomical and functional brain modularity.

Anatomical Brain Networks

Modular organization at the anatomical level has been studied in both animal studies and human studies. In animal studies of the cat and the macaque, whole-brain anatomical connectivity has been obtained in tracer studies (Hilgetag et al. 2000). A network partition procedure identified four subnetworks, classified as the visual, auditory, somatosensorimotor, and frontolimbic systems (Hilgetag et al. 2000). This was an early example that the general notion of modularity recovers some of the basic assumptions within functional neurology and neuroanatomy. Another study that uncovered the modularity in mouse, rat, macaque, and human connectomes showed that most communities are assortative, while others form core-periphery and disassortative structures (Betz et al. 2017). Assortative communities are those composed of nodes with similar features (e.g., numbers of connections or “degree”). Core-peripheral communities are those with a densely intra-connected set of nodes with typically fewer peripherally connected nodes. Disassortative communities are those where nodes with quite different

Evidence of Brain Modularity,

Fig. 2 Schematic of hubs. A “provincial” hub (red) is a node with high connectivity with other nodes within a module. A “connector” hub (purple) is a node that connects multiple modules to one another

nodal features are associated with one another. Thus, within major networks in the brain, diverse roles in regulating information within communities can be observed, forming different putative roles in cognitive processes that are associated with variations in human performance (Betzel et al. 2017).

In human *in vivo* neuroimaging studies, modularity has been examined in anatomical networks constructed from diffusion tractography used to estimate cortical and subcortical connectivity. Examining anatomical network organization also helps us understand the functional networks commonly observed using functional neuroimaging techniques.

Modularity in anatomical brain networks can be observed early during brain development (Fan et al. 2011). The anatomical networks of early developing brains have small-world topology and nonrandom modular organization like that of adult brain networks. The so-called default-mode network is one of several major brain networks that emerges during the developmental phase from infancy and matures during brain development from adolescence to adulthood. The network activates “by default” even when a person is not involved in a task. Anatomically, the default-mode network consists of the dorsal medial subsystem and the medial temporal lobe subsystem. Like all brain networks, the default-mode network is a large-scale brain network of interacting brain regions known to have activity highly correlated with one other and distinct from other networks in the brain.

The density of connections in the brain increases from early development to adulthood, but reduces during the rest of the life-span, leading to sparsity in the module connections (Betzel et al. 2014). The brain starts developing into modules at early development, and it continues through adolescent years. As an adult, the brain is developed into modules with functional relevant roles with dense connections between modules. As we age, through the rest of the life-span, the brain experiences age-related changes leading to sparsity in the connections between the modules, potentially reducing intermodular communication and cognitive flexible performance (Song et al. 2014; Monge et al. 2017).

Modularity in anatomical networks also differs across the sexes. One study that involved a connection-wise analysis showed that male brains are structured to facilitate intra-hemispheric cortical connectivity, in the entire brain, except in the cerebellum (Ingallhalikar et al. 2014). Male brains have enhanced local, short range within-lobe connectivity. Networks in the male brain are more transitive, modular, and discrete to facilitate the within-lobe and within-hemispheric connectivity. Transitivity is characterized by the connectivity of a region to its neighbors. Male brains have higher transitivity than female brains which indicate that their brains have a greater disposition of nodes to form numerous strongly connected communities. Female brains are structured to facilitate higher interhemispheric connectivity. The connection-wise analysis was also used to examine gender differences during development. The connectivity profiles showed that adolescent and young adult males had higher intra-hemispheric connectivity and same-aged females had higher interhemispheric connectivity. This confirms that modularity in the brain networks begins from early development helping to form functionally independent modules in adult brains.

Anatomical network partitions exhibit a community structure that reproduces some functionally specialized networks, such as visual, auditory/language, somatosensorimotor, and superior parietal systems (Meunier et al. 2010). Moreover, anatomical network modularity shapes much, but not all, of the activity observed in functional modular networks (Honey et al. 2009; Hermundstad et al. 2013; Medaglia et al. 2017; Real et al. 2017; Sethi et al. 2017). However, modularity in some functional brain networks exceeds what can be interpreted from anatomy alone; thus, we need behavioral and cognitive manipulations linked to the connectivity to better understand the modularity in the brain.

Functional Brain Networks

As anatomical brain networks help us understand the stable connections in the brain that facilitate communication among regions, functional brain networks help us understand the neurophysiological dynamics of the brain. Modularity in

functional brain networks can be inferred from neural measurements such as those acquired during BOLD-fMRI imaging or from electrophysiological recording (EEG/MEG).

Functional MRI (fMRI)

The functional modules that are observed during rest using functional MRI form identifiable resting networks that organize task-related activity. This phenomenon has been observed in a few studies (Fig. 3).

Certain brain networks such as the frontal-parietal brain network are widely recruited in a variety of cognitively demanding tasks. The dorsolateral prefrontal cortex (DLPFC) is the area in the prefrontal cortex of the brain which is involved in executive functions such as working memory, cognitive flexibility, decision-making, inhibition, and abstract reasoning. An example of the behavioral task is the combined

A-not-B/delayed response task, in which the subject finds a hidden object after a certain delay. This task requires holding information in mind, that is, using the working memory, which is one of the functions of DLPFC. Thus, the frontal-parietal brain networks are highly flexible and variably connected in the brain, which allows the frontal-parietal brain networks to use multiple networks when performing a task (Cole et al. 2013).

In another study, a region-to-region information mapping procedure was applied to real fMRI data to test its ability to infer cognitive information transfer in the human brain (Cole et al. 2016). Using a novel experimental task design meant to manipulate cognitive complexity, the brain network analysis utilized within-region vertex-level activation patterns along with vertex-to-vertex resting-state functional connectivity between regions to predict information content in each region – a measure of “flow” across the

E

Evidence of Brain Modularity, Fig. 3 Module organization example from fMRI. (a) Parcel communities: Communities identified with a community detection algorithm using the boundary map-derived parcels as network nodes. (b) Network structure of the brain calculated using every

voxel as a network node. (c) Spatial overlap of the voxel-wise and parcel wise community assignments. (Figure and caption reproduced with permission from Gordon et al. 2016)

network. A region-to-region information transfer matrix was computed that represented the region-to-region information transfers at the network level. Significant region-to-region information transfers were detected in all tasks suggesting that resting-state functional connectivity is relevant to cognitive task activations due to its role in shaping task-evoked activity flow among brain regions. Thus, resting-state functional connectivity topology describes the channels of information transfer across multiple functional networks and across multiple task content domains.

Another finding by Cole et al. (2016) was that regions within the frontoparietal network collectively act as flexible hub networks to communicate task-based demands in different cognitive domains. Individual differences in intrinsic network activity flow helped explain individual differences in cognitive task activations. In addition, the reconfiguration efficiency of the functional connectivity between specific networks and the rest of the brain is significantly correlated with performance. The efficiency of some networks was related to performance on specific tasks (language task, reasoning task, and a working memory task), whereas other networks were associated with performance across multiple tasks. Efficiency in the salience network may reflect the ability to integrate and process multimodal information important for guiding behavior across a variety of task demands.

Another study showed that the cognitive control networks are global hubs, allowing for efficient information transfer across the brain. Functional and anatomical connectivity analyses illustrate that the default-mode network regions are the strongest global hubs. Using novel statistical methods with resting-state fMRI, high connectivity was demonstrated in both the cognitive control network regions and the default mode network regions. This within-module network connectivity changes can be one hallmark of cognitively relevant brain activity (Sridharan et al. 2008; Ito et al. 2017; Medaglia et al. 2018).

Brain modularity varies across people, suggesting that the amount of information segregation and integration across the entire brain

varies among people. Modular variability is related to the level of difference in the cognitive performance across individuals (Bassett et al. 2013; Yue et al. 2017). Cognitive performance is measured during cognitive processes that support sequential, goal-directed behavior.

A graph theoretic measure called the participation coefficient considers how a region's links are distributed across modules. When network links for regions are distributed across different modules (participation coefficients close to one), they help regulate intermodular communication between individual brain regions. Regions with low participation coefficients (close to zero) play a greater role in effecting communication patterns within their own module. Regions with high participation coefficients are considered parts of the default mode, salience, control, and attention networks suggesting that higher-order cognitive systems might owe parts of their functionality to the fact that their components span multiple modules and can efficiently integrate information from those sources (Betz et al. 2016).

Electrophysiological Techniques

Electrophysiological techniques are another way to measure the functional connectivity and modularity in brain networks. EEG and MEG have high temporal resolution but low spatial resolution, forming a natural complement to BOLD fMRI. Modularity in brain networks can also be observed using electrophysiological techniques. In one study, MEG electrodes were used to measure levels of synchronization in the delta to gamma frequency bands in a resting-state task in healthy individuals. Undirected unweighted graphs obtained by thresholding matrices of synchronization likelihood values showed that in the delta, theta, and gamma (>30 Hz) frequency bands, functional networks exhibited the property of "small-world networks." This showed that the brain might be organized for efficient information processing, connecting different brain areas (modules) by connections in the brain (Stam 2004). In another MEG study analyzing the connectivity structure in normal brains, brains of healthy individuals exhibited sparse connections between modules (Chavez

et al. 2010). These results suggest that modularity plays a key role in the functional organization of brain areas, maintaining relative specialization of individual modules.

EEG studies have also identified the presence of small-world networks (Micheliyannis et al. 2006). The small-world nature of the EEG networks is negatively correlated with the level of intellectual functioning. The small-world character of EEG networks is also decreased in students (aged 21–26 years) compared to children (8–12 years) in the beta and gamma bands. Thus, the “small-world” network organization is observed in this study as well from early development to adulthood (Micheliyannis et al. 2009).

Modules and the Mind

In a cognitive context, Machery suggested a “massive modularity hypothesis” (Machery 2007). The massive modularity hypothesis proposes that the human mind consists of many innate, domain-specific modules. These modules have putatively evolved due to natural selection and are functionally distinct. Many cognitive competences such as choosing one’s food habits, spatial navigation, seeing, and face recognition are supported by the modules. However, the routing and domain-integration demands in certain cognitive tasks have caused many commentators to challenge this pure modularity of the mind. For example, there are some cognitive tasks such as reading which could use many modules together or support “domain-general” and integrative processes in cognition (Carruthers 2006). Moreover, the shared variance among cognitive domains across individuals has been argued to suggest that domain-general mechanisms must exist or alternatively that the parts that compose one domain’s function contribute to multiple domains (Rabaglia et al. 2011). While these debates are ongoing, a fundamental issue remains whether and how cognitive modules map to empirically detected brain modules. However, there are several potential evolutionary advantages to brain modularity in general even if their precise cognitive relevance has not been fully clarified.

Evolutionary Origins and Selection of Brain Modularity

Brain modularity may directly or indirectly provide an organism with survival and reproductive advantages. Specifically, as described above, modularity balances specialized and integrated processing. Modular networks can engage in specialized information processing, perform focal functions, and support complex neural dynamics. In addition, modularity provides functional robustness and may in principle make the brain more naturally adaptable. Aging and disease lead to a decrease in brain modularity which reduces the ability of these systems to respond to external stress. Modular brain systems are more robust because the effect of harmful perturbations can be isolated to specific modules. In addition, if one module fails, the rest of the brain may be left relatively unaffected by having other modules perform the lost function. Thus, the brain is neuroplastic. Once a neural system evolves a basic modular architecture, it can facilitate further evolutionary adaptation. Components of modular systems can evolve semi-independently because different parts of system can be optimized separately without drastically interfering with the functioning of other parts. Moreover, different modules can be combined to create new functions. Within a modular system, information can be stored in pieces or swapped in large chunks from one module to another (Lorenz et al. 2011).

A key constraint on brain evolution concerns the energy costs and geometric constraints associated with specific brain network configurations. The wiring cost of the brain network is a fundamental trait that contributes to the brain’s modular organization (Betzel et al. 2016). The brain’s restricted energy resources form a constraint on connection lengths, which becomes skewed in favor of low-cost connections. Some features of brain modularity suggest that evolution has provided an economical wiring solution that optimizes modularity under this constraint. Brain networks favor short-range connections that densely connect nearby areas, which contribute on key aspect to the modular clustering observed

in “small-world” brain networks, facilitating local processing. However, the brain still has a small number of long-range connections which have been preserved over the course of evolution. These connections are a result of the trade-off between the formation of connections that reduce the network’s wiring cost and those that improve its functionality. Long-distance connections are extremely important for brain function, because they improve the efficacy of interregional communication and information transfer by reducing the average number of processing steps in the network, mediating communication through many hubs in the brain. This means that they are highly involved in the shortest paths across brain networks. Long-distance connections are also disproportionately observed along the brain’s longest axis, facilitating communication all the way from the anterior frontal cortex to the visual cortex. Thus, evolutionary selection has favored economical, modular brain networks that facilitate robust, flexible, and adaptive processing throughout the organism’s life-span and over evolutionary time.

Conclusion

Like many biological organisms and systems, the human brain exhibits modularity from early development to adulthood. In adulthood, the modules become refined and perform tasks under diverse demands to achieve goals. Brain modularity potentially provides evolutionary fitness by providing specialized, modifiable, and robust bases for cognitive functions. Thus, modularity in the human brain is a pervasive, dynamic, and essential phenomenon throughout the life-span.

Synonyms

Lethal Aggression; Lethal Conflict; Warfare; Murder

Definition

Psychological adaptations for using physical force or other lethal strategies to eliminate another individual or a group of individuals, either by oneself or as part of a coalition, with death occurring not as an accidental consequence of wounds or injuries that were meant to intimidate or subjugate.

Introduction

The question of whether or not a killing is *intentional* is problematical. In cases of nonhuman animals, we have no way of even asking whether they intended to kill another; in the case of humans, we have no way of determining objectively whether their claims of intentionality (or lack thereof) are veridical. A more objective definition of intentional killings would be restricted to those killings which appear to represent the direct adaptive function of the violent aggression that produced it, as evidence of having been shaped by selection to produce that specific outcome.

In this context, the study of lethal and nonlethal conflict and aggression aims to assess why aggressive interactions take place and who is likely to use

violence against whom, under what socio-ecological circumstances and, importantly, when killing is itself adaptive, rather than simply inflicting injuries, intimidating, and subjugating through violence. Violent behavior is usually activated to counter threats to survival and reproductive prospects. Competition and conflicts of interest over resources thus elicit aggression, potentially with lethal consequences, between rivals. Evolutionary logic is employed as a theoretical framework for investigating whether certain types of or dispositions for violent behavior are adaptive, and whether killing (not only injuring, fending off, or intimidating) serves functions or if it is a neutral or even maladaptive byproduct of such aggressive dispositions. Various different forms of and motives for lethal aggression are reviewed.

Review

From an evolutionary perspective, the capacity for engaging in violent conflict with conspecifics is understood as an adaptation and not as pathology (Lorenz 1966; Wilson 1978). Killing itself, however, has been proposed to frequently be the dysfunctional tail of a distribution of adaptive violent responses; in this view, the killing is a byproduct of the violent behavior being deployed to coerce the behavior of a conspecific, where death is not necessarily the objective of the violence (Daly and Wilson 2003; Ferguson 2011). As such, some argue that killing can be seen as too drastic a resolution for interpersonal conflicts, and not what adaptive mental mechanisms were selected to lead to in terms of outcomes. However, a specific adaptation view is supported by several lines of evidence indicating that killing does in fact facilitate gene-copying success in various circumstances, as we review below, although less extreme behavioral outputs of the same aggressive motives (e.g. competition for resources and for mates, defense of honor and reputation, etc.) may often be sufficient to promote reproductive success.

To study aggression and killing in sufficient detail, the distinction is frequently made between in-group and out-group killings (de Waal 1989).

This distinction is not only scientific (*etic*) but also culturally (*emic*) most societies discriminate between attacking and killing within the community and attacking and killing outgroup members. In many cultures (including our own), the latter form of aggression is frequently seen as positive and commendable, and thus as a service to the community, whereas within-group attacks are morally condemned and agents are seen as perpetrators, murderers, abusers, criminals, and deviants, rather than as courageous warriors and heroes fighting for a cause. The differences in attitudes and terms used to view and describe these two forms of conflict betoken a fundamental difference in the psychology of aggression. Within-group attacks may reduce cohesion, whereas between-group attacks may motivate the unity of the community and facilitate the pursuit of common goals. Thus these different forms of aggression and killing are theorized to be subjected to distinct selection pressures and to affect fitness differently, as different socioecological circumstances and adaptive problems are involved in within- and between-group conflicts.

Reasons for Conflict and Killing Within Groups

As with other manifestations of conflict, discussing the nature and possible adaptive functions of intragroup aggression remains a highly controversial topic. Descriptions of socioecological pressures that select for intimate partner violence, within-group coalitional violence, or infanticide still generate heated discussions concerning the forces that shape such phenomena phylogenetic, their status as pathological, and the phylogenetic ubiquity of these behaviors. For researchers not endorsing an adaptive view of intragroup lethal aggression, it is interpreted as either (1) the maladaptive byproduct of exacerbated individual aggression (Daly and Wilson 2003), (2) a manifestation of failed impulse control or an underlying psychopathological condition (Gottfredson and Hirschi 1990), or (3) an abnormal social behavior associated with unusual demographic pressures or a mismatch between ancestral environments of adaptive relevance and current environments (such as modern, industrialized societies in humans, or captivity in

nonhuman primates; Ferguson 2011). Furthermore, for this approach, high reported rates of fatal violence within primate species are considered an uncommon phenomenon, with researchers behind it proposing that the number of cases claimed is an overestimate based on indirect and inferential methods of tally.

Alternatively, special adaptation hypotheses of within-group killings consider the fitness benefits obtained by attackers (Buss and Duntley 2003; Hrdy 1979). Adaptationist explanations of the intragroup aggression that may lead to killing critically depends upon an assessment of the costs and benefits of life-threatening violence. These assessments must be made in comparison and contrast with any other available instrumentalities for resolving social conflicts. Furthermore, the cost-benefit tradeoffs that lead to lethal intragroup aggression may vary from individual to individual, where one individual might be more liable to incur lower costs or more likely to accrue higher benefits than another by employing interpersonal violence. These variations might be attributable to the individual costs and benefits of the aggression, but they might also be attributable to those of the alternatives to aggression. For example, if one individual is deficient in social skills or general cognitive capacity, they might be more prone to adopt a violent than a nonviolent alternative to solve challenges due to individual incompetence in solving the adaptive social problem nonviolently. These considerations lead to an examination of the sociodemographics of lethal aggression within groups.

Examples of possible fitness benefits of killing are ascending in the dominance hierarchy, achieving high status, eliminating rivals who would otherwise compete for resources or mates, decreasing the coalitional power of competitors, and gaining access to food patches. Lethal aggression within groups is not restricted to intrasexual aggression between adults. Full-grown individuals also target unweaned younglings, with attackers obtaining benefits such as restarting the ovarian cycle of females who are unreceptive during gestation or lactation, acquiring and retaining mates, and decreasing competition. Empirical support for these adaptive hypotheses

have accumulated in the scientific literature (► [“Humans: Within-Group Conflicts”](#) in the chapter by Fernandes et al., this volume; ► [“Non-human Primates: Within-Group Conflicts”](#) in the chapter by Peñaherrera-Aguirre et al., this volume).

Intragroup hostility jeopardizes the successful implementation of long-term mating strategies, continued investments among kin, and the maintenance of long-term cooperative and community efforts, thus reducing interindividual cohesion within groups in several senses (Figueredo and Jacobs 2009). However, the maintenance of social features is prioritized by individuals and groups in relatively stable, predictable environments in which cumulative and future payoffs to current investments can be prioritized. Conversely, within-group hostile and deviant behavior is expected to be a feature of individuals who have little to lose and who can have little certainty of future rewards of long-term investments in cooperation, and in familial and social cohesion. As such, higher rates of interpersonal violence are observed to be associated with risk-proneness, impulsiveness, and overall fast life history.

Reasons for competition for resources or partners which may elicit aggressive behavior exist mostly within each sex, as the two sexes differ to a considerable extent on what they aim to obtain (Buss and Shackelford 1997; Muller and Wrangham 2009). Considering the sex differences in reproductive capacity and reproductive cycles, variance in reproductive success is more variable among males than among females; mammalian males can be expected to compete more for reproductive access to females than the reverse. Males are thus more likely than females to be physically violent, be it in interindividual interactions or in warfare between groups, being equipped with anatomical, physiological, and psychological features that permit more successful violent behaviors. Females do not lack motivations for competition and aggression, and are clearly observed to engage in such interindividual interactions across primate species and human societies, due to basically the same socioecological predictors as males. Between-sex altercations, however, clearly lead to a preponderance of

injuries inflicted upon females, due to differences in strength and in the capacity to sustain damage. Intense competition among males, nevertheless, is not widespread across mammal taxa, rather being more prevalent in species with promiscuous or polygynous mating systems. Among humans, it can be expected to be more prevalent among those which prioritize short-term mating strategies and which are exposed to less stable and predictable social ecologies (Figueredo and Jacobs 2009).

Infanticide is not frequently observed in primate species and has never being observed in the wild in some taxa (e.g. orangutans; Knott et al. 2010). It is nevertheless present in diverse mammalian clades and human cultures. Infanticide is most commonly committed by unrelated males or by mothers. Proposed sources of adaptive value (Daly and Wilson 1988; Hrdy 1979) for infanticide of unrelated offspring include elimination of a competitor's genes from the population's gene pool and increased access to potentially fertile females who would otherwise be investing in the offspring rather than in reproductive activity. In contexts of infanticide of related offspring, potential sources of increased fitness include: (1) higher chances of parental survival, considering the life history tradeoff being parental and offspring health (especially in cases of poor parental health, famine, abandonment by one of the parents and absence of social support); and (2) increased chances of parental reproductive success, in cases of ill-timed, severely handicapped, or supernumerary offspring (as sacrificing an infant under such conditions would permit investing more resources in other offspring or in future reproduction). As such, infants at greater risk of infanticide are those who: (1) exhibited noticeable physical or mental problems; (2) were born too close in time to older siblings or in too large a litter, imposing demands on limited parental resources; (3) were born to a mother with little or no social support, especially if she is young and can thus prioritize investments in future reproduction, sacrificing current but unfavorable reproductive output; and (4) are more exposed to unrelated adult males, or if adulterous conception is suspected by the investing male. To reduce the likelihood of infanticide of their offspring by unrelated males, adult female primates of many taxa have been argued to evolve
